Objectives

The objective of this report is to significantly increase field-wide production in the Spraberry Trend in a short time frame through the application of preferred practices for managing and optimizing water injection. Our goal is to dispel negative attitudes and lack of confidence in water injection and to document the methodology and results for public dissemination to motivate waterflood expansion in the Spraberry Trend.

Germania Spraberry Field Demonstration Status

The water injection began on Feb 3, 2003 from six injectors. The six injectors consist of three wells converted to water injection (17, 407A and 410A), two wells returned to water injection (11W and 22W) and a new injection well (214W) as shown in Fig. 1. We developed preferred management practices based on all prior experience in the ET O'Daniel Pilot Area and also based on the response measured during old water injection performance as discussed in previous report (Schechter et al, 2003). We monitor the water injection response by associating the water injection rate with the expected response in near-trend and on-trend producers as presented in Table. 1. An average of 270 bpd water is injected through each of those six injectors (Fig. 2). Up to now some wells have responded to water injection. Production GSU well 308A has increased from average 10 bopd to 19 bopd (Fig. 3). The water production from this well shows almost similar response to oil production rate, which indicates this well is strongly dependent on water injection. However, as of this date other wells still do not show a definite response.

In order to observe the response of water injection, we also included the wells outside the Germania Lease as shown in Fig. 4. These wells were included to track the response of water injection since the water injection may travel to great distance as observed in our previous work in ET O'Daniel Pilot Area. Oil, water and gas production are carefully monitored in wells along the entire perimeter of the area expected to respond within the Germania Unit. The production rate history of on-trend and off-trend wells were totaled and plotted prior to water injection as can be seen in Figs. 5 and 6. These production data will be updated until the end of the project. Any increase in oil production during the waterflood period will be identified and used for our economic analysis.

Development of Reservoir Management Database Software

Properly managing a reservoir that is so large and communicates, via the fractures, over great distances, poses a complicated technological and data management constraint. This problem acts as a deterrent for waterflood operations in Spraberry reservoirs. Reservoir engineering, by definition, requires precise injection, production and pressure data. Acquisition and control of this data has always been a constraint to providing the optimum method for water injection. The result is large volumes of oil that could have been recovered via water injection remain untapped. We believe by proper data

acquisition and precise reservoir engineering techniques, any lack of confidence in waterflooding can be overcome.

In this report period, even though we are still using Oil Field Manager (OFM™) as our production database system, we are also developing our own database system to perform a better analysis for this particular area. This database software is written using a visual basic programming language. It has the capability to perform similar tasks as the OFM database system such as decline curve analysis, material balances, bubble map plot and in addition it would have unique features such as plotting the ellipse map following the fracture trend, PVT analysis, risk analysis, well trajectory and simulation.

This program would be applicable for any type of reservoir. The current progress is intended to show the use of this program for managing the data in the Germania Unit. Fig. 7 shows the front page of the database software. The production and injection input data format follows the TOW data format for an easy access updating of the production data. Figure 8 shows the result of uploading the well location, well information, and production/injection data. Once we have uploaded the well data, we can zoom-in and zoom-out the picture to find specific information on a certain well in the cluster location (Fig. 9). The zoom-in result can be seen in Fig. 10. By pointing the cursor to a certain well, the menu bar in the right hand side shows some information on the selected well. For the wells that have a different status, we created a note at the bottom as seen in Fig. 11. Figure 12 shows the two menu bars, Task menu and Petroleum Tools menu. Task menu consists of production history, data entry and a well diagram. Figure 13 shows an example of the production history of well 1-Meek C with unique API, surface location and present operator. We can view the data graphically by clicking the view chart button in the table. In the graph dialog, we can perform decline analysis with a user-defined range. We have three options for decline analysis: exponential, harmonic and hyperbolic declines. We can also allow the program to select the best-fit option automatically based on extended Spivey algorithm (1986). The example of decline curve analysis using hyperbolic option is presented in Fig. 15.

In addition, Petroleum Tools has several engineering applications such as PVT (Figs. 16 and 17), directional survey (Figs. 18 and 19), bubble mapping and material balances (Fig. 20). We are going to add more features in this menu in the near future.
