## Abstract:

A prototype of a tritium thermoelectric generator (TTG) is currently being developed at Sandia. In the TTG, a vacuum jacket reduces the amount of heat lost from the high temperature source via convection. However, outgassing presents challenges to maintaining a vacuum for many years. Getters are chemically active substances that scavenge residual gases in a vacuum system. In order to maintain the vacuum jacket at approximately  $1.0 \times 10^{-4}$  torr for decades, non-evaporable getters that can operate from  $-55^{\circ}\text{C}$  to  $60^{\circ}\text{C}$  are going to be used.

This paper focuses on the hydrogen capacity and absorption rate of the St707<sup>TM</sup> non-evaporable getter by SAES. Using a getter testing manifold, we have carried out experiments to test these characteristics of the getter over the temperature range of  $-77^{\circ}\text{C}$  to  $60^{\circ}\text{C}$ . The results from this study can be used to size the getter appropriately.

## **Introduction:**

Sandia is developing a thermoelectric generator that uses tritium as the heat source. A vacuum is used to minimize heat loss from the source through convection. In high-vacuum environments, residual gases can accumulate as a result of outgassing. A getter is a chemically active substance which scavenges any traces of impurities in a vacuum system [1-3]. To maintain a vacuum of approximately  $1.0 \times 10^{-4}$  torr over many years, a non-evaporable getter is used. Non-evaporable getters require no power during use. In the tritium thermoelectric generator (TTG), the getter is required to operate from  $-55^{\circ}\text{C}$  to  $60^{\circ}\text{C}$ . A prototype of the TTG is shown in Figure 1 [4]. In order for the getter to be activated at a high temperature, it is placed in a remote location from the main body of the TTG. The goal of our study is to measure the absorption capacity of the St707™ non-evaporable getter at temperatures between  $-77^{\circ}\text{C}$  and  $60^{\circ}\text{C}$ . This will allow us to approximate the amount of getter required to sustain the vacuum in the TTG. At the same time, these tests will enable us to determine the gettering rate.

**Figure 1. Prototype of the tritium thermoelectric generator.**

The St707™ non-evaporable getter is a ternary alloy  $\text{Zr}_{57}\text{V}_{36}\text{Fe}_7$  composed of 70% Zirconium, 24.6% Vanadium, and 5.4% Iron by weight [5, 6]. This getter type was chosen because of its ability to operate at room temperature. Since hydrogen is one of the most abundant residual gases in vacuum systems [7], we have tested the St707™ non-evaporable getter for both its capacity and absorption rate for hydrogen over the temperature range of  $-77^{\circ}\text{C}$  to  $60^{\circ}\text{C}$ . The results of our study can be used to estimate the amount of getter required to sustain a high vacuum for decades.

## **Experimental:**

### **Getter Activation**

Before the getter can be tested for gas absorption, it must be activated. A non-evaporable getter has a protective passivation layer that is produced during its manufacture. In the activation process, the passivation layer dissolves into the bulk of the getter, exposing the surface of the getter and making gas sorption possible.

The getter was placed in a stainless steel reaction vessel. The steel reactor has a valve that allows the sample to be isolated from the surrounding environment. Both the reactor and the valve have conflat mini flanges sealed with a copper gasket. To measure the temperature of the sample, a Type-K thermocouple was spot-welded to the side of the vessel.

Using a turbomolecular pump (Pfeiffer Vacuum TCM 180), the reaction vessel was first evacuated. Then, the reactor was inserted so that the getter was in the center of the furnace. The getter was baked at 200°C for two to three days. The set point of the furnace was then raised to 400°C, and the sample was kept at this temperature for 45 minutes for activation. The setup of the activation process is shown in Figure 2. Pressure and temperature data were acquired using the WorkBench PC™ program by Omega Engineering, Inc. After activation, the sample is transferred under vacuum to the getter testing manifold.

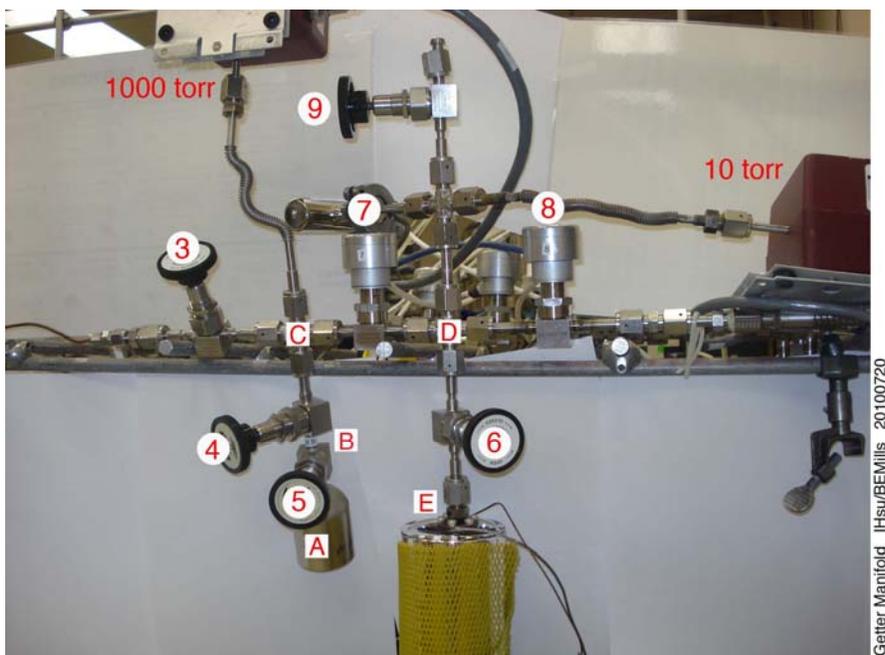

**Figure 2. Schematic of getter activation setup. The railing allows for the position of the reaction vessel inside the furnace to be adjusted.**

### **Hydrogen Capacity Testing**

The basic apparatus used to test getters was designed and built at Sandia [8]. The manifold consists of both manual and pneumatic valves, and is shown as a photograph in Figure 3 and as a schematic in Figure 4. The pneumatic valves are controlled by computer-activated solenoids, and are labeled as 7 and 8 in the schematic. In Figures 3 and 4, the volumes shown are designated as A through E and are 102.5 mL, 3.9 mL, 13.0 mL, 20.8 mL, and 38.3 mL respectively. The manifold is equipped with both a turbomolecular pump and a separate roughing pump. The pressure readings were initially taken using 10 torr and 1000 torr Baratron® pressure transducers, both of which were manufactured by MKS Instruments, Inc. These transducers were used for the

tests run at  $-77^{\circ}\text{C}$  and  $60^{\circ}\text{C}$ . For the experiment run at  $20^{\circ}\text{C}$  (room temperature), additional 1 torr and 0.02 torr pressure transducers were installed at Volume D on the getter manifold for a greater degree of accuracy. This allows for further pressure readings to be taken even after the 10 torr and 1000 torr transducers have reached their lower limits. Each time a change was made to the system, the affected volumes were re-measured. These new values were then incorporated in the calculations for the quantity of hydrogen absorbed at the different temperatures. For all of the experiments, pressure and temperature data were recorded using the LabVIEW™ 6i data acquisition program.

The St707™ non-evaporable getter samples we used had a diameter of 0.396 inches, a height of 0.125 inches, and a mass of approximately 1.19 grams. To test the hydrogen uptake capacity of the getter, the steel reaction vessel (Volume E) containing the sample was attached to the manifold. The manifold was first evacuated and flushed with hydrogen. 99.99999% pure hydrogen gas was produced with a hydrogen generator by Parker Analytical Gas Systems. For each of the different temperatures at which the getter was tested, multiple trials were carried out. For each trial, Valve 7 was kept closed while Volumes A through C were filled with  $\sim 18$  std  $\text{cm}^3$  hydrogen. The gas was then expanded into Volume D and given time to equilibrate. Finally, Valve 6 was opened, initiating the absorption of hydrogen by the getter in the vessel.

**Figure 3. A photograph of the getter testing manifold with pressure transducers, valves, and designated volumes A-E indicated.**

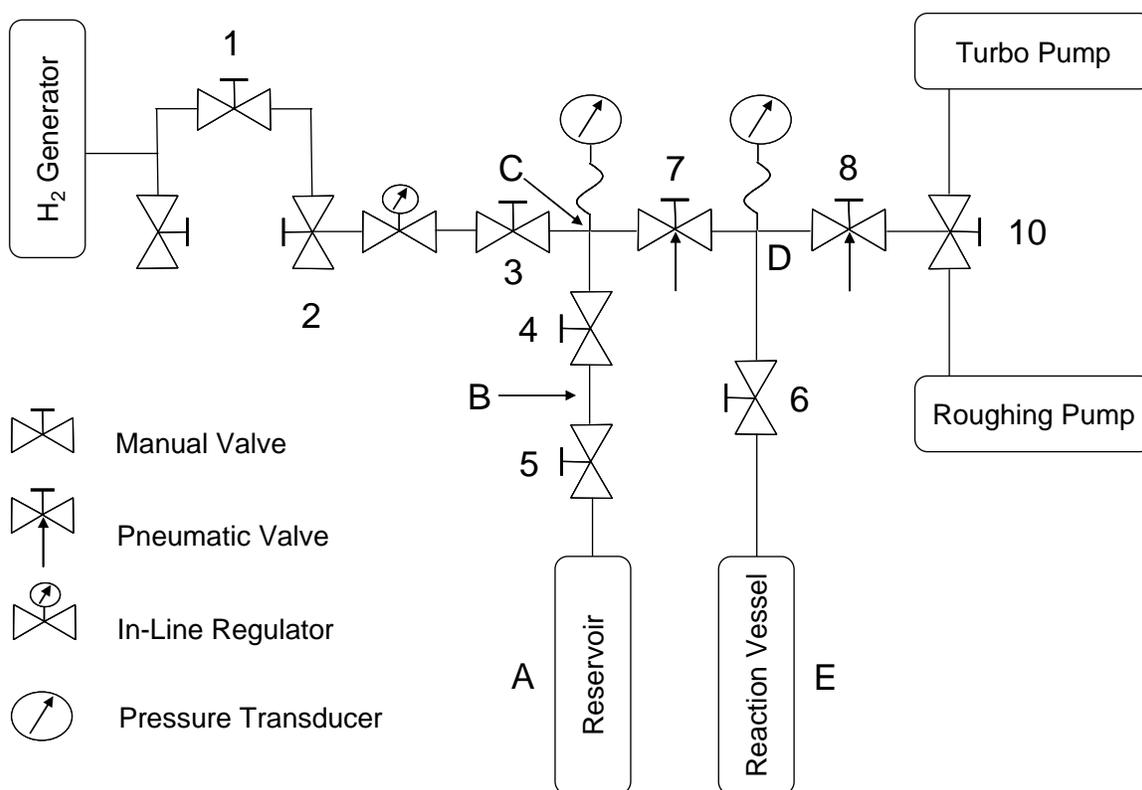

Figure 4. Schematic of getter testing manifold.

### Obtaining Different Temperatures

Different methods were used to obtain the temperatures at which the tests were conducted. For 60°C, a heating mantle was laced around the reaction vessel to apply heat to the container. A Type-K thermocouple was placed between the mantle and the vessel, and the set point of the heating mantle was adjusted to the desired temperature. The amount of heat applied by the mantle was based on the reading given by the thermocouple.

Originally, an attempt was made to create a slush bath at -55°C using a mixture of *m*-xylene and *o*-xylene. Although we could achieve -55°C, it was not possible to maintain a stable temperature for an extended period of time. Therefore, it was decided to use dry ice in acetone, a mixture at the sublimation temperature of CO<sub>2</sub> with the acetone remaining in liquid form at all times. By submerging the reaction vessel in a Dewar containing dry ice and 250 mL acetone, a temperature of -77°C could be achieved. Pellets of dry ice were periodically added to maintain the temperature.

## **Results:**

The hydrogen capacity of the St707<sup>TM</sup> non-evaporable getter was tested at -77°C, 20°C, and 60°C. A total of four experiments were performed, including a preliminary experiment carried out at room temperature (20°C). In the preliminary test, 223.4 std cm<sup>3</sup>/g hydrogen was taken up, and the final stabilized pressure was 397.2 torr. These values provided an overall indication of the quantity of hydrogen that can be absorbed by the getter. For each of the subsequent tests, multiple trials using aliquots of approximately 18 std cm<sup>3</sup> hydrogen were carried out. Each trial was terminated when the pressure in the manifold stabilized. The experiments at -77°C, 20°C, and 60°C were terminated at pressures of 13.9 torr, 16.2 torr, and 0.314 torr, respectively.

A summary of the results of each trial at -77°C is shown in Table 1. The hydrogen capacity is given in std cm<sup>3</sup>/g. To determine the std cm<sup>3</sup> of each trial, the number of moles of hydrogen absorbed was used along with the values of STP (Standard Temperature and Pressure) set by the National Institute of Standards and Technology (NIST). For STP, NIST uses a temperature of 293.15 K and an absolute pressure of 1 atm. The capacity is also given in moles of hydrogen absorbed per gram of getter. Figure 5 shows the pressure change during the first seven minutes of every trial as equilibrium is approached. This shows the initial kinetics for each trial. There is a distinct transition in rate at about 15 seconds; this transition becomes less prominent during later trials. During this experiment, the lowest pressure that could be measured was with a 10 torr Baratron<sup>®</sup> pressure transducer, which cannot reliably make measurements at the smallest pressure indicated in Figure 5.

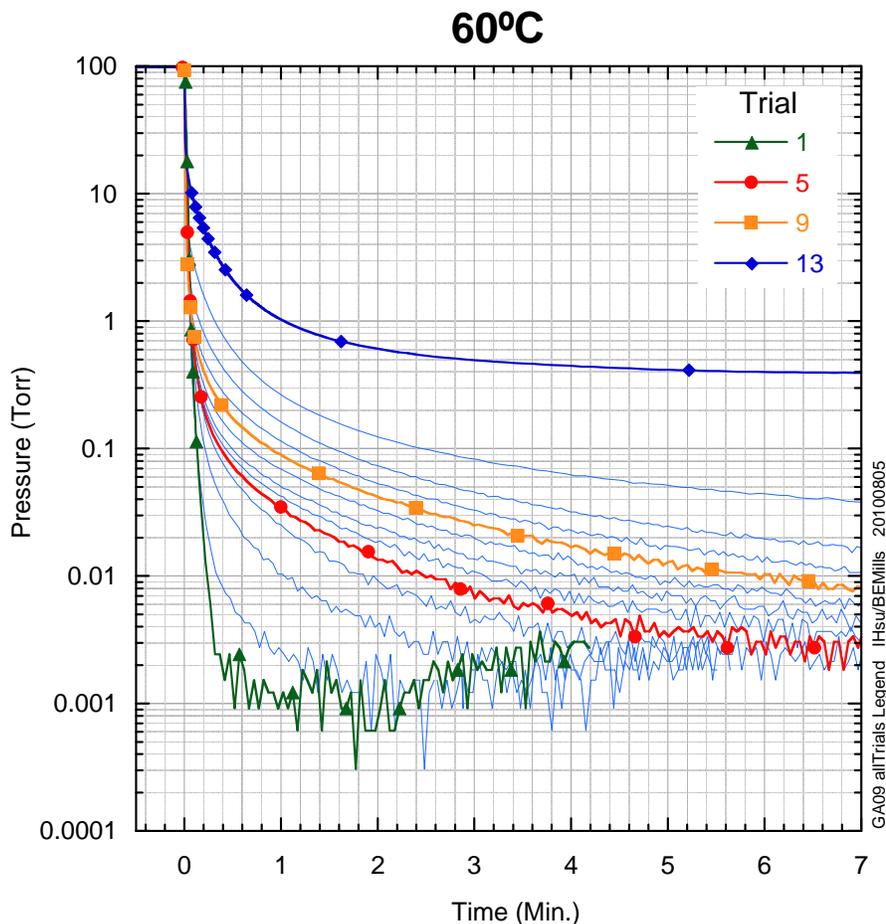

**Figure 5. Comparison of pressure change over time for each trial in the -77°C experiment.**

The results of each trial performed at 60°C are summarized in Table 2. Both the pressure at 1 minute and the time taken to reach 0.01 torr gradually increased with each subsequent trial. A representation of the kinetics for the first seven minutes of each trial is shown in Figure 6. The distinct transition in absorption rate seen in the -77°C experiment is not as evident in this case. A more asymptotic approach to equilibrium is observed.

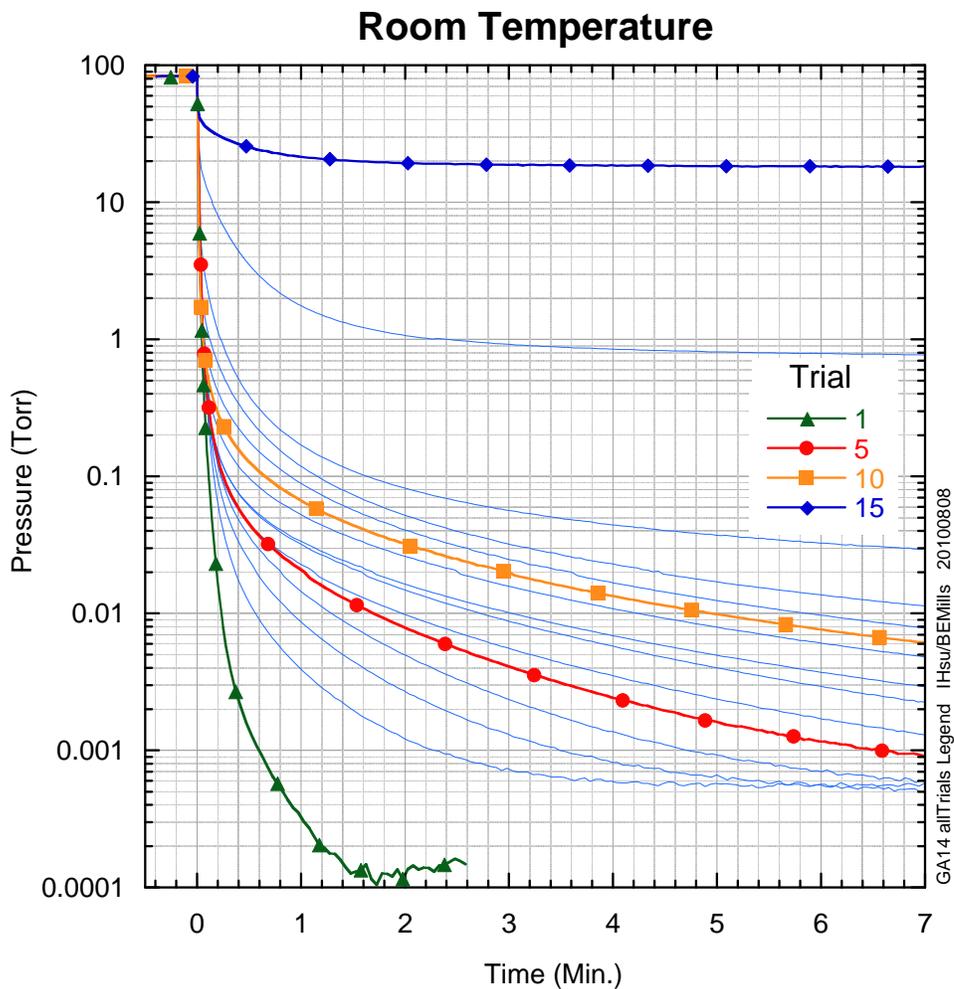

**Figure 6. Comparison of pressure change over time for each trial in the 60°C experiment.**

For the second experiment that was carried out at 20°C (room temperature), additional 1 torr and 0.02 torr pressure transducers were installed at Volume D on the getter manifold. This allowed the pressure in the system to be measured with a higher degree of accuracy. Because new transducers were added, Volume D had to be recalculated by running volume expansion tests using hydrogen. The new value for Volume D was determined to be 45.6 mL. Table 3 summarizes the results of each trial at room temperature, and Figure 7 gives a representation of the gettering rate for the first 7 minutes of each of the 15 trials performed. The plot shows how the absorption kinetics changed throughout the course of the experiment. In trial 1, the getter was able to achieve a pressure of 0.0001 torr, lower than that of any other trial. The first trial was terminated after only 2 minutes and 36 seconds had elapsed, a shorter period of time than any of the subsequent trials.

As in the 60°C case, the room temperature experiment shows a gradual transition in rate, in contrast to the more distinct transition in rate seen in Figure 5 for the -77°C experiment.

**Table 3. Hydrogen capacity and pressure data for each trial at 20°C.**

| Trial | H <sub>2</sub> Capacity (std cm <sup>3</sup> /g) | Cumulative H <sub>2</sub> Capacity (std cm <sup>3</sup> /g) | Cumulative Mol H <sub>2</sub> /g | Pressure at 1 Minute (torr) | Time Taken to Reach 0.01 Torr (min) |

**Figure 7. Comparison of pressure change over time for each trial in the 20°C experiment.**

In all of the experiments, the time taken to reach 0.01 torr increased monotonically (Figure 8). On the initial trials, the getters at room temperature and 60°C are approximately an order of magnitude faster in pumping down to 0.01 torr than the getter at -77°C. At a cumulative total of 90 std cm<sup>3</sup>/g, the rates of the getters at 60°C and -77°C became identical. In comparison, the rates of the room temperature and -77°C experiments became identical at a cumulative total of ~125 std cm<sup>3</sup>/g. After these points of intersection, the -77°C experiment, which had previously changed little in rate, displayed faster kinetics than both the other two experiments. Furthermore, we see that after a cumulative total of 165.86 cm<sup>3</sup>/g, the 60°C getter stopped achieving a pressure of 0.01 torr. The room temperature getter ceased to pump down to 0.01 torr after 182.02 cm<sup>3</sup>/g. In contrast, the getter tested at -77°C is able to achieve 0.01 torr until it reaches a capacity of 224.69 std cm<sup>3</sup>/g.

A similar way of visualizing the variation in rate between the different experiments and different degrees of hydriding is seen in Figure 9, where the pressure at 1 minute is plotted against the cumulative std cm<sup>3</sup>/g. The plot shows that the getters at 20°C and 60°C are initially able to

achieve a lower pressure at a faster rate than the getter in the cold experiment (-77°C). Starting from trial 9, however, the kinetics of the cold experiment surpassed the kinetics of the other two experiments. As with the time taken to reach 0.01 torr, the pressure at 1 minute for all of the temperatures at which the getter was tested shows a monotonic increase. In both Figures 8 and 9, the lines on the plots are terminated when the experiments are ended. Overall, the greatest number of trials was carried out at -77°C, indicating that the capacity of the getter was the highest at this temperature.

In general, the absorption behavior and kinetics of the room temperature experiment were more similar to those of the experiment performed at 60°C. Both of these experiments also show a more gradual progression to equilibrium than the -77°C experiment.

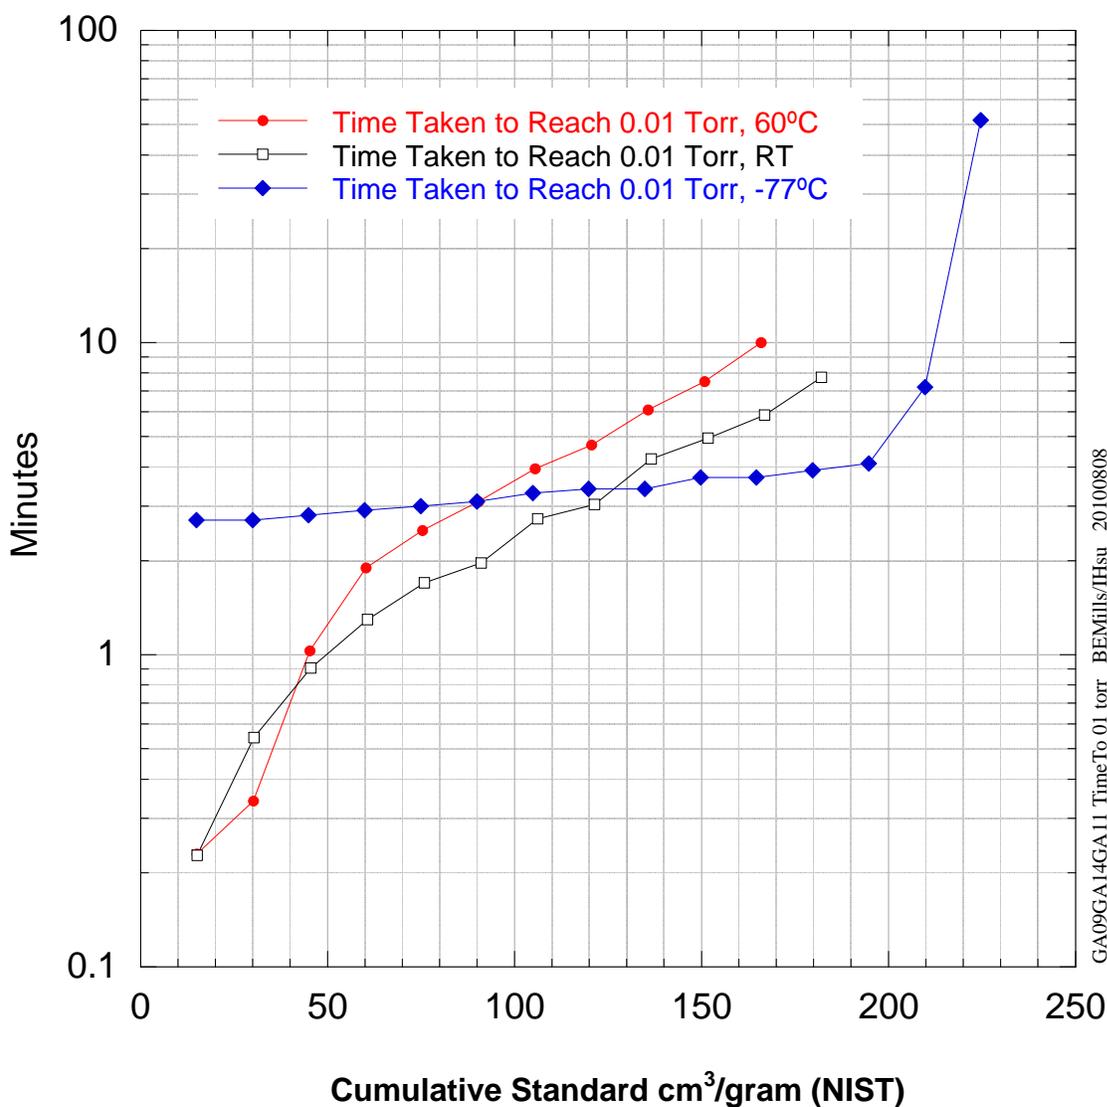

Figure 8. Comparison of the time taken to pump down to 0.01 torr for each temperature at which the getter was tested.

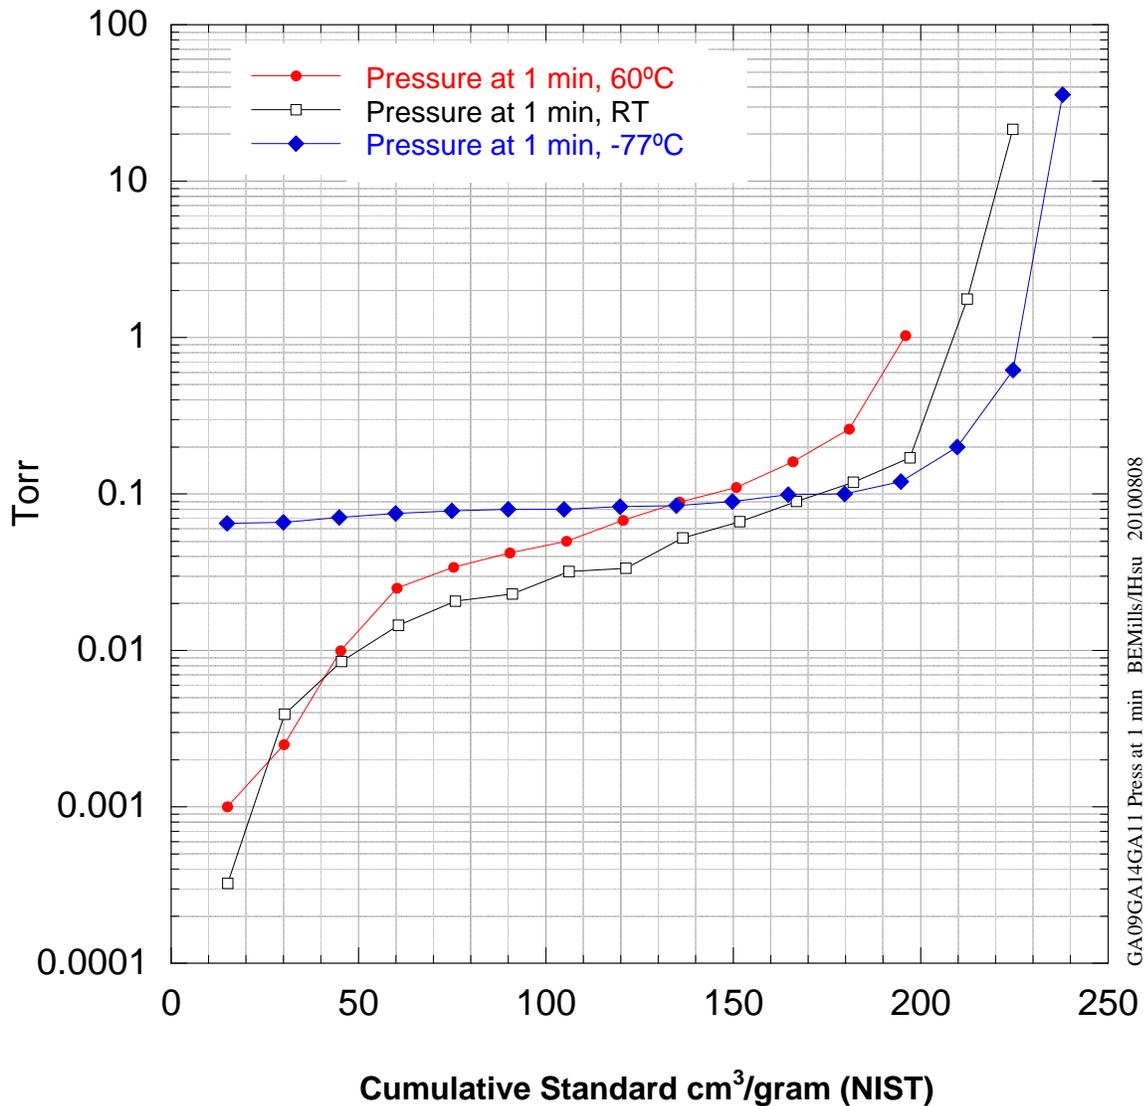

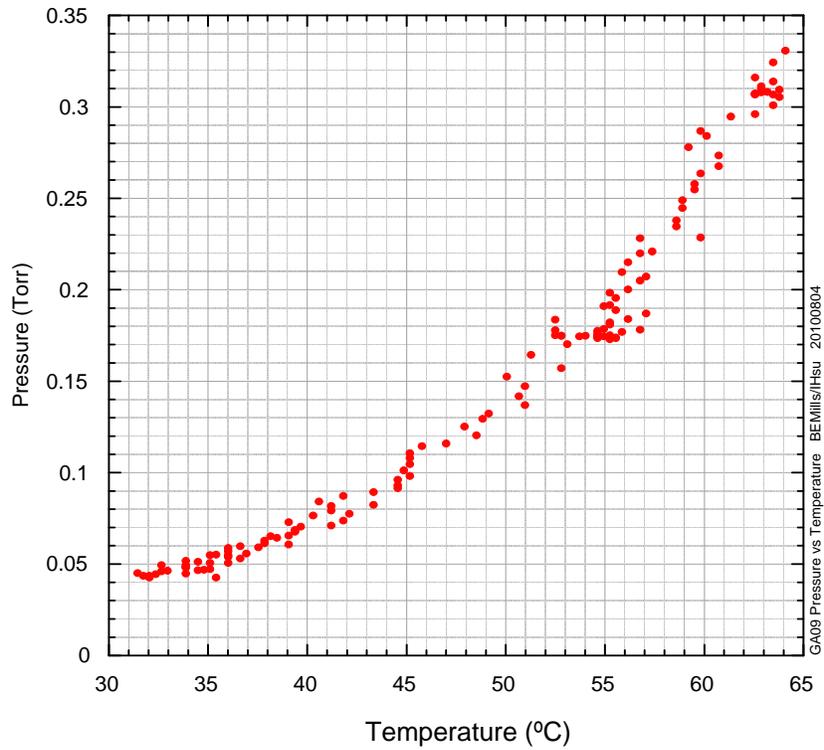

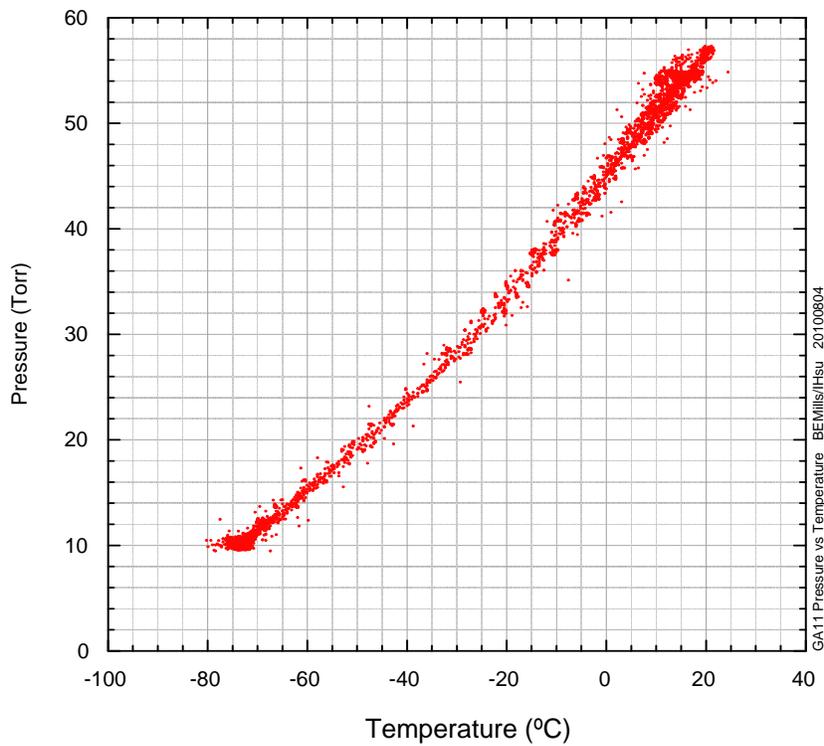

Figure 9. Comparison of the pressure at 1 minute for each experiment.

### Analysis of Pressure and Temperature

After completion of the -77°C and 60°C experiments, the getter was allowed to return to room temperature while the pressure was still being measured. For the experiment at -77°C, the relationship between the pressure and temperature is shown in Figure 10. The relationship between the pressure and temperature for the 60°C experiment is shown in Figure 11. The decrease in capacity at elevated temperatures is consistent with the expected change in the width of the plateaus in the PCT (pressure-composition-temperature) diagram [9] of the zirconium-hydrogen system.

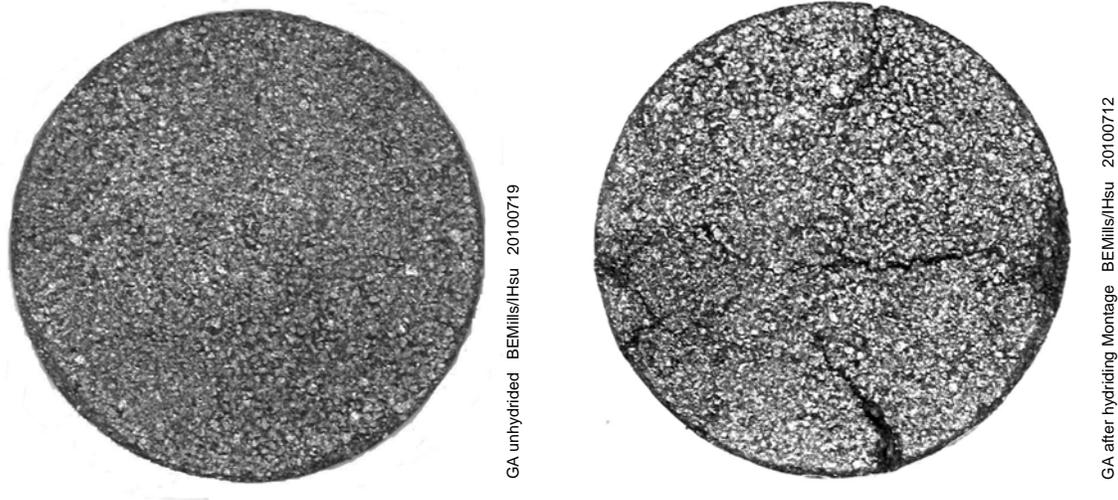

**Figure 10. Relationship between temperature and pressure from cooling the getter after the 60°C experiment.**

**Figure 11. Relationship between temperature and pressure from the getter warming to room temperature after the -77°C experiment.**

Hydrogen reacts exothermically with zirconium to form zirconium (II) hydride. For each of the different temperatures at which the getter was tested, an increase of 1°C was observed for the first few trials. As the getter hydrided, its density decreased [10], causing cracks to form (Figure 12). Eventually, most of the getter material crumbled into powder.

## **Conclusions:**

As the results show, the capacity of the St707<sup>TM</sup> non-evaporable getter is the greatest at the lowest operating temperature, -77°C. By using the ratio of moles of H<sub>2</sub> absorbed to moles of Zr in the getter, the number of hydrogen atoms taken in by each Zr atom can be determined. The resulting value of “X” in ZrH<sub>X</sub> therefore gives an indication of the relative effectiveness of the getter. The inverse relationship between temperature and capacity is shown through the gradual increase in the H<sub>2</sub> to Zr mole ratio as the temperature decreases. At lower temperatures, the sample can more effectively retain a larger amount of gettered gas. A summary of the hydrogen capacity of the getter at different temperatures is shown in Table 4.

**Table 4. Summary of hydrogen capacity of getter across all experiments.**

| Operating Temperature | Quantity H <sub>2</sub> Absorbed (mol/g) | Capacity (std cm <sup>3</sup> /g) | H <sub>2</sub> to Zr Mole Ratio |
|-----------------------|--|-----------------------------------|---------------------------------|
| -77°C                 | 9.88×10 <sup>-3</sup>                    | 237.85                            | 1.29                            |
| 20°C                  | 9.33×10 <sup>-3</sup>                    | 224.54                            | 1.22                            |
| 60°C                  | 8.14×10 <sup>-3</sup>                    | 195.96                            | 1.06                            |

Overall, the absolute absorption rates across all of the trials were very fast, regardless of temperature. The hydrogen in the manifold was taken in by the getter within minutes, more than adequate for a vacuum system which will outgas on the scale of decades. Based on the outgassing load to the vacuum, the capacity and rate measurements made in this study can be used to size the getter appropriately for a life span of many years. These parameters will be further tested at other temperatures with different gases and types of getters.
