ABSTRACT

LACROIX, ANDREW THOMAS. Evaluation of Different Methods for Populating the LTPP Materials Database with Dynamic Modulus. (Under the direction of Dr. Y. Richard Kim).

The *NCHRP 1-37A Guide for Mechanistic-Empirical Design of New and Rehabilitated Design Structures* introduces the dynamic modulus ($|E^*|$) as the material property to characterize asphalt concrete. This is a significant change from the resilient modulus (M_R) used in the previous AASHTO Pavement Design Guide. One of the challenges of changing the material characterization is that databases, such as the Long Term Pavement Performance (LTPP) Materials Database, contain older material characterization information. Therefore, databases must be updated to the currently accepted standard. This thesis evaluates two methods to populate the LTTP database with $|E^*|$ values: 1) determine the $|E^*|$ from different geometries (i.e., cores and prisms) and 2) predicting the $|E^*|$ from the measured M_R values in the database.

Acquiring the $|E^*|$ from existing pavements is difficult due to the standardized dimensions of the test specimen. Other geometries, indirect tension specimens and prismatic specimens, have been tested to determine if the measured $|E^*|$ is statistically different from the modulus obtained from the AASHTO TP 62 protocol. This study provides a comparison of the effects of a non-uniform state of stress and anisotropy. These effects are isolated by comparing specimens prepared by Superpave gyratory compaction and vibratory steel-wheel compaction. The results in the thesis are verified using four 12.5 mm surface course mixtures with different aggregate types and binder types, and one 25.0 mm base mixture. The results are verified using volumetric variations such as different percentage of aphalt cement and air voids. The results show that the

difference between the $|E^*|$ values obtained from different geometries is statistically insignificant. The results provide justification for using alternative methods for acquiring the $|E^*|$ experimentally, specifically from previously constructed pavements.

Practioners prefer a mathematical model since measuring the $|E^*|$ is a time and labor intensive. The second section of this thesis presents an artificial neural network (ANN) to predict the $|E^*|$ from the measured M_R. The first step is an analytical method of calculating the M_R from the $|E^*|$. It involves the application of multiaxial linear viscoelastic theory to linear elastic solutions for the indirect tension test developed by Hondros (1959). The results show that the predicted and measured M_R values are in close agreement. The results provide a forward model for the back-calculation of the $|E^*|$ from M_R. Using this forward model, a database of measured dynamic moduli is populated with corresponding predicted resilient moduli to train an ANN. The trained ANN is the back calculation model used to predict $|E^*|$ from measured M_R. The dynamic moduli predicted from the measured resilient moduli using the trained ANN are found to be reasonable compared to the measured dynamic moduli.

Evaluation of Different Methods for Populating the LTPP Materials
Database with the Dynamic Modulus

DEDICATION

This thesis is a testament to many people who have constantly encouraged me to stretch and grow as I have journied along my academic career.

The primary influence on my academic career is my parents, Michael and Carol LaCroix, who have shown me the joys of learning a multitude of topics. Probably the most important lessons were about my faith in God, which has given me the strength to keep moving even when it seemed all was lost.

Professors Fr. Thomas McShane and Dr. Michael Cherney in the Department of Physics at Creighton University have encouraged me to succeed and explore new topics such as cellular automata and encouraged me to branch out into engineering.

Dr. E. Terence Foster, a professor of Construction Systems in the College of Engineering at the University of Nebraska at Omaha who provided me with the encouragement and guidance to use my physics background as a firm grounding for the applications of civil engineering.

The final influence has been Dr. Y. Richard Kim since he was willing to take a chance to train a physics student to research transportation materials.

BIOGRAPHY

Andrew LaCroix was born in Greensboro, North Carolina to Michael and Carol LaCroix. After nine months there, his family moved to Albemarle, North Carolina, where they lived for nine years. Then the family moved to Reading, Pennslyvania, living there three years. His family then moved to Omaha, Nebraska, where he lived for ten years. Living in the Heartland of America strongly shapes who he since he completed sixth through the completion of his undergraduate degree in Omaha. The attitude of someone from the Heartland is honesty, directness, and simplicity. His attitude toward life is generally relaxed with the belief that God will provide all his needs. He graduated from Omaha Central High School in May 2001 with honors. He then remained in Omaha to attend Creighton University to earn a Bachelor of Science in Physics magna cum laude in May 2005.

   After graduating from Creighton, Andrew returned to North Carolina to start graduate school at North Carolina State University. The return to North Carolina reinforced an important aspect of Andrew's life: the Korean connection. Andrew's grandparents were education missionaries to Korea from the 1950's to 1990. At North Carolina State University, Andrew found himself in good company since his advisor, Dr. Kim, and several lab partners were Korean. Also, Andrew's wife, Amanda, was adopted from Korea. The Korean connection is strong and may influence where Andrew works in the future.

ACKNOWLEDGEMENTS

The most important person to acknowledge is my wife, Amanda. Without her encouragement, patience with long and crazy hours, helping sieve, and watching movies at the CFL, the research for this thesis would not be possible. I also acknowledge my parents for their encouragement and understanding when I vented about the number of differents tasks I have done over the years.

A special thanks to Christopher Capp and Jessica Allison of Duke University for being my adopted brother and sister, especially the first year of graduate school.

The most critical group of people for accomplishing the research were my lab partners. Shane Underwood has been a great mentor, especially by challenging me to think about the problem differently and solving many mechanical problems, many times by opening the right drawer. Sangyum Lee has been a great friend who could make me smile when it was what I needed most. The graduate students of Dr. Kim's, Tae Young Yun, Cheol Min Baek, Jae Jun Lee, Ju Sang Lee, Fadi Jadoun, and Ardalan Mosavi Khandan, are appreciated for providing encouragement and coffee throughout the research process.

Several professors were instrumental in teaching me. Dr. Kim provided the needed guidance, encouragement, and big picture to complete the study. Dr. Ranji S. Ranjithan taught me the concept of ANN. Dr. Arellano guided me in using statistics to determine conclusions from a large database with several interactions.

CHAPTER 1 INTRODUCTION

In mechanistic or mechanistic-empirical pavement design and analysis methods, it is

essential to know the properties of the layer materials. These material properties define a

basic relationship between the stresses and strains in the various layers. The 1993

AASHTO Pavement Design Guide employs the resilient modulus (M_R) as the material

property representing the stiffness characteristics of layer materials. The M_R is defined as

the ratio between applied stress (σ_a) and recoverable strain (ε_r); that is,

$$M_R = \frac{S_a}{e_r}.$$
(1.1)

Several testing standards have been developed for the determination of the M_R of asphalt

concrete using the indirect tensile (IDT) test method (ASTM D4123, NCHRP 1-28,

SHRP P-07, NCHRP 1-28A).

One of the major changes in the recently developed *NCHRP 1-37A Guide for*

Mechanistic-Empirical Design of New and Rehabilitated Design Structures, compared to

the 1993 AASHTO Guide, is that the dynamic modulus (|E*|) is used as the material

property to characterize asphalt concrete. This transition from M_R to |E*| may make a

significant amount of the M_R data that have been collected in state highway agencies

obsolete, unless a method to measure the |E*| from existing pavements is developed or a

method to convert M_R values to |E*| is developed. One good example of a database with

M_R values obtained from numerous cores taken from in-service pavements is the Long

Term Pavement Performance (LTPP) Materials Database. This thesis evaluates two

methods to populate the LTPP database with |E*| values: 1) determine the |E*| from

different geometries (*i.e.*, cores and prisms) and 2) predicting the |E*| from the measured

M_R values in the database.

1.1 Measuring Dynamic Modulus with Different Geometries

The first major challenge to populating the LTPP materials database with |E*| is

acquiring the material property from existing pavements. For example, the LTPP

materials database has cores from many different pavements, but many cannot be cut and

cored to the standard dimensions for measuring |E*|. The AASHTO TP-62 standard

decribes a method to determine the |E*| and phase angle of hot mix asphalt (HMA)

specimens using an axial compression load. In the standard, a specimen is a cylinder 150

mm (about 6.0 in.) tall and 100 mm (about 4.0 in.) in diameter. The height is greater than

some thin pavements, which means the specimen cannot be cored from the surface of the

pavement. Also, thicker asphalt concrete pavements are usually composed of several

layers (such as base, intermediate, and surface layers). These layers may have different

|E*| values, so the ability to characterize the |E*| for each layer from these cores is

questionable.

Kim *et al*. (2004) evaluates the possibility of using IDT testing to measure the |E*| of

existing asphalt concrete pavements by comparing the |E*| values from the IDT tests

against those from axial compression tests on standard cylinders. Twelve asphalt

mixtures were used in the verification study. Considering the fact that IDT specimens are

38 mm (1.5 in.) in thickness and can be cored from a pavement, IDT tests are a viable

option for testing material properties of existing pavements. However, IDT specimens are

not the only option for testing materials from pavements. Pavements can be trench cut,

and the resulting cross sections can be cut or cored into specimens similar to the axial specimens used in the AASHTO TP-62 standard. In light of this fact, a prismatic column (prism) geometry is also considered in this study.

Several challenges are addressed in Chapter Five to evaluate the possibility of accepting IDT and/or prism testing as an alternative to standard cylinder. Kim *et al.* (2004) recognized that two main differences exist between IDT and axial compression tests. One difference is the uniaxial stress state in axial compression versus the biaxial state of stress in IDT. The other difference is the relative directions of compaction and stress-strain analysis. For axial compression tests on specimens compacted by the Superpave gyratory compactor (SGC), the directions of compaction and stress-strain analysis are identical. On the other hand, SGC-produced IDT specimens are tested perpendicular to the compaction direction. In an anisotropic mixture, the aggregate within a mixture tends to have certain orientations based on the method of compaction (Hunter *et al.*, 2004, Tashman *et al.*, 2004). The anisotropic aggregate structures resulting from SGC compaction could affect the stress-strain analysis. Another source of anisotropy is the effect of SGC versus field compaction, because specimens for measuring |E*| for existing databases are removed from pavements in the field. The total difference between the field IDT and laboratory axial compression measurements could be due to the effect of anisotropy because of the differences in state of stress, different directions between the compaction and the stress-strain analysis, and/or the compaction method.

For this study, these differences are investigated along with the differences between axial and prism compression testing. The comparisons in this section are based on

recommendations in a white paper by Schwartz (2004). Chapter Five of the thesis presents experimental results to determine whether the |E*| can be measured from different geometries and compaction methods, as well as possible limitations that might exist for implementing this method as a standardized test.

1.2 Predicting Dynamic Modulus from Resilient Modulus

The LTPP materials database can be populated with |E*| values in a less rigorous, though less accurate method than measuring |E*|. Practioners desire a model to predict |E*| since measuring |E*| is a time and labor-intensive process. Currently, several predictive models of |E*| exist, such as the Witczak model (Bari and Witczak, 2007) and the Hirsch model (Christensen *et al.*, 2003). These models use a variety of inputs such as binder properties, HMA volumetrics, and aggregate information. One of the measured mixture properties available in the LTPP materials database is M_R. Therefore, is important to develop a relationship between M_R and |E*| to populate the LTPP material database with reasonably accurate values of |E*|. Such a method has further benefit since some asphalt materials and pavement analysis methods still require the M_R as an input.

M_R provides a snapshot of the material behavior under one loading history (i.e., a 0.1 second haversine loading followed by a 0.9 second rest period) at different testing temperatures (normally three temperatures at 5°, 25°, and 40°C). Most attempts to develop the relationship between M_R and |E*| so far have been empirical in nature, such as setting a correlation between |E*| and M_R values at a frequency of 5.2 Hz (Loulizi *et al.*, 2006). Other relationships involve trying to predict the material property using mechanical theory, such as two-phase micromechanical relationships (Li and Metcalf,

2005). Zhang (1996) explored the possibility of characterizing the viscoelastic properties from M_R tests using Fourier analysis. It was concluded that this type of analysis is impractical due to: 1) the difficulty in solving a large number of variables and, 2) the limited range of results, providing slightly more time-temperature characterization than M_R data. Another challenge is that Fourier analysis requires a loading and deformation history for optimizing the viscoelastic parameters, which most databases do not contain. Therefore, any attempt to predict the $|E^*|$ from the M_R is, at best, empirical in nature. The hypothesis of this study is the prediction of the M_R from the $|E^*|$ can be made using the theory of viscoelasticity.

The sixth chapter of the thesis presents an analytical approach to predict the M_R from the $|E^*|$. Experimental results provide evidence that the concept is valid. Because the M_R of asphalt concrete is normally determined using the IDT test, analytical, viscoelastic solutions are developed for the IDT test configuration. It involves the application of multiaxial linear viscoelastic theory to linear elastic solutions for the IDT test developed by Hondros (1959). Since the ultimate purpose of this study is to populate the LTPP materials database with $|E^*|$ values, the linear viscoelastic solution is used as a forward model (*i.e.*, $|E^*|$ is used to predict M_R) for the back-calculation of $|E^*|$ from M_R.

Using the forward solution method, a database of measured dynamic moduli, such as the Witczak database, is populated with corresponding predicted resilient moduli to train an artificial neural network (ANN). Once a database is populated with predicted M_R values, predictive relationships can be developed using optimization techniques, such as the artificial neural network (ANN). The trained ANN is the back calculation model used

to predict |E*| from measured M_R. Further information regarding the use of neural networks in pavement applications can be found in Xu *et al.* (2002).

CHAPTER 2   MATERIAL PROPERTIES

2.1 Dynamic Modulus (|E*|)

|E*| is one of the three fundamental material properties that can be used in the linear viscoelastic constitutive relationship. E* is the complex modulus, which is composed of the storage and loss modulus, as shown in Figure 2.1.
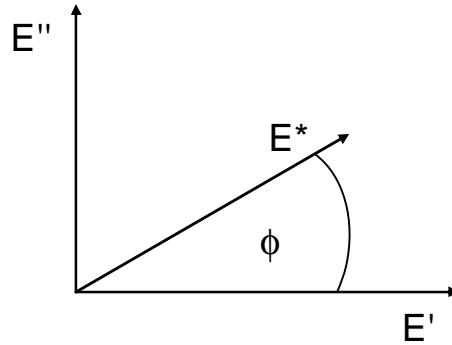

Figure 2.1 Graphical Represenation of E*.

The complex modulus, E*, is represented as follows:

$$E^* = E' + iE'',$$
(2.1)

where

|E*| = magnitude of E*;

E'   = storage modulus = |E*| cos ϕ;

E"   = loss modulus = |E*| sin ϕ.

The storage modulus represents the storage (elastic) component of energy of the response. The loss modulus represents the damping and energy loss of the system during the material response. The other two material properties are creep compliance, D(t), and

the relaxation modulus, E(t). Due to their fundamental nature, theoretical relationships exist among these three material properties that have been proven valid for the characterization of asphalt concrete (Kim and Lee, 1995). The storage modulus (E'), can be represented in terms of a Prony series as seen in Equation (2.2). Knowing E' is important for predicting the stress response to a given strain history.

$$E'(w_r) = E_\infty + \sum_{i=1}^{n} \frac{w_r^2 r_i^2 E_i}{w_r^2 r_i^2 + 1},$$ (2.2)

where

E_∞ = elastic modulus (MPa);

ω_r = angular reduced frequency;

E_i = modulus of the ith Maxwell element; and

ρ_i = relaxation time of the ith Maxwell element.

Since most |E*| tests are load-control tests, D(t) is needed to predict the strain response from a stress history. An exact conversion to D(t) can be obtained by solving the following equations:

$$[A]\{D\} = \{B\}, \text{ or } A_{kj}D_j = B_k$$ (2.3)

$$A_{kj} = E_\infty \left(1 - e^{-(t_k/t_j)}\right) + \sum_{i=1}^{m} \frac{r_i E_i}{r_i - t_j}\left(e^{-(t_k/r_i)} - e^{-(t_k/r_i)}\right) \quad r_i \neq t_j,$$ (2.4)

and

$$B_k = 1 - \left(E_\infty + \sum_{i=1}^{m} E_i e^{-(t_k/r_i)}\right) \bigg/ \left(E_\infty + \sum_{i=1}^{m} E_i\right).$$ (2.5)

where,

A_{kj} = matrix element in the kth row and j^{th} column of matrix A;

B_k = vector element in the kth row of vector B;

E_∞ = equilibrium modulus (MPa);

E_i = modulus of the ith Maxwell element;

r_i = relaxation time of the ith Maxwell element determined *a priori*;

t_j = retardation time of the jth Voigt element determined *a priori*

t_k = time of interest; and

m = number of Prony coefficients.

By solving for D_j, the Prony series representation for D(t) can be determined. Equation (2.4) does not show a solution for $\rho_i = \tau_i$ since the error increases when such a case exists (Park and Schapery, 1999).

Since the behavior of viscoelastic materials is dependent on time, rate of loading, and temperature, these material properties are determined at multiple rates of loading and multiple temperatures (in degrees Celsius) as seen in Figure 2.2.
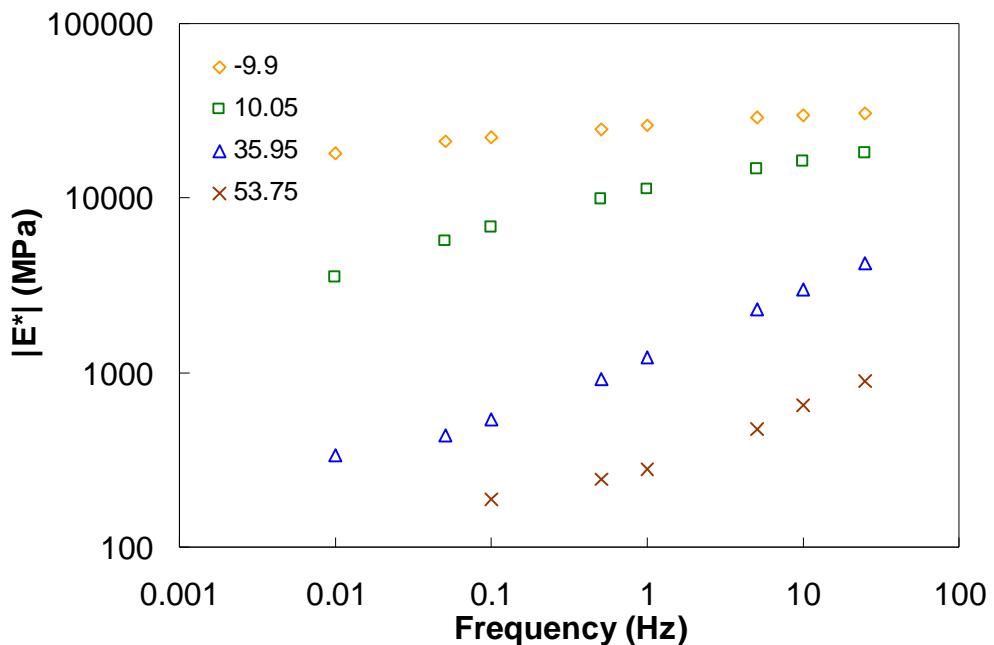

Figure 2.2 Example of measured |E*| values at different frequencies and temperatures.

A single, continous curve is developed using the time-temperature superposition

principle. The principle states that rheologically simple materials, such as HMA, can be

shifted in the time or frequency domain (i.e., the horizontal axis) to produce a single,

continuous curve. The equation for the shifted frequency, known as the reduced

frequency, is:

$$f_r = a_T f \tag{2.6}$$

where

$\quad$ f $\;=$ frequency (Hz); and

$\quad$ f_r = reduced frequency.

$$\log(a_T) = a_1 T^2 + a_2 T + a_3 \tag{2.7}$$

where

$\quad$ a_1, a_2, and a_3 = coefficients; and

$\quad$ T $\qquad\quad$ = temperature.

The |E*| values are shifted according to Equations (2.6) and (2.7) to produce a continuous

curve called a mastercurve. Before shifting, a reference temperature is selected such that

$\log(a_T)$ is zero. The result is a curve that provides the relationship between shift factors

and temperature as seen in Figure 2.3 with a reference temperature of 10°C.
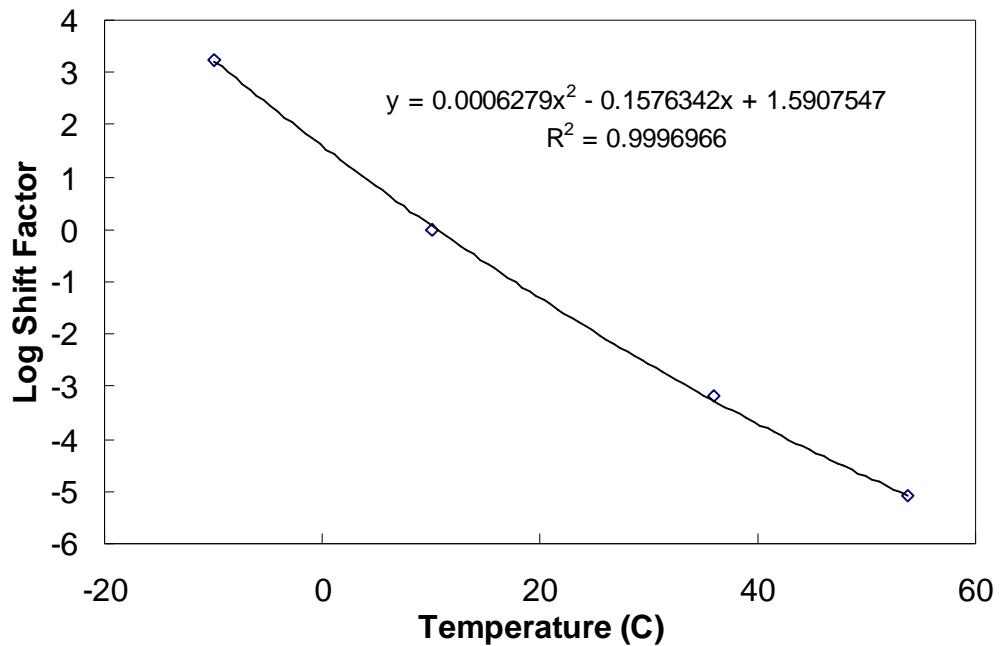

Figure 2.3 Example of a temperature shift factor curve.
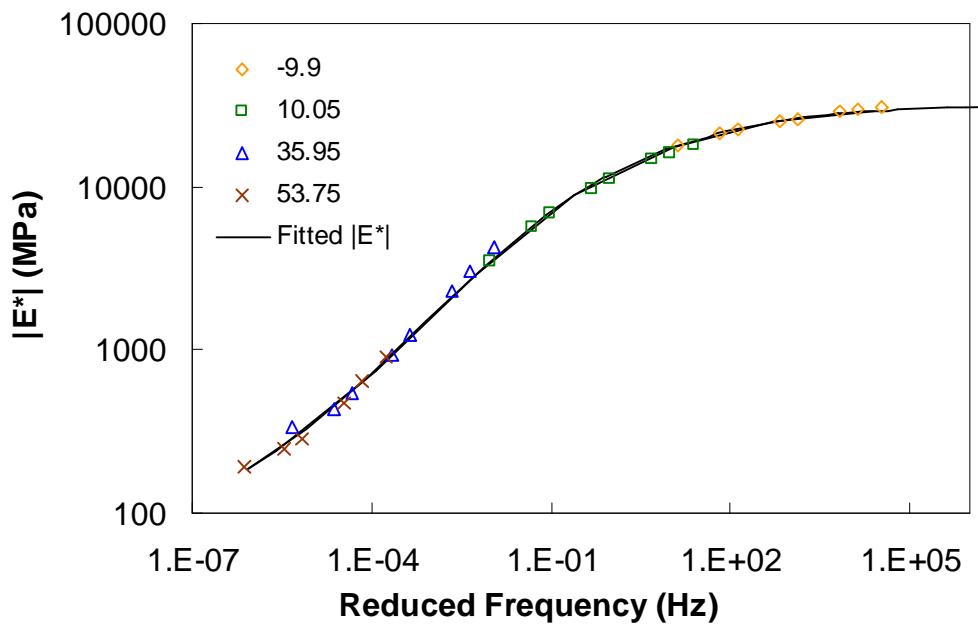

Figure 2.4 Time-temperature shifted |E*| mastercurve.

As seen in Figure 2.4, the horizontal shifting of the |E*| values in Figure 2.2 produces a

mastercurve. The mastercurve is represented by a sigmoidal function, Equation (2.8),

which was selected to compensate for variability that might be present in the data.

$$\log | E^* |= a + \frac{b}{1 + \dfrac{1}{e^{c+d*\log(f_r)}}} , \qquad (2.8)$$

where

a, b, c, d = constants; and

f_r = reduced frequency.

The reduced frequency represents the testing frequency needed to produce the |E*| value

at the reference temperature. The benefit of time-temperature superpoisiton is the ability

to predict the material response at temperatures and frequencies other than the measured

values. To determine the |E*| at a different temperature and/or frequency, calculate the

reduced frequency to find |E*| from the mastercurve sigmoidal equation.

2.1.1 |E*| Using Axial Compression

Axial compression is a uniaxial state of stress in the plane of loading. Axial and prism

specimens are loaded in the uniaxial manner. Equation (2.9) shows the simple

formulation of calculating the |E*| from uniaxial measurements.

$$| E^* |= \frac{s_o}{e_o} , \qquad (2.9)$$

where

σ_o = steady-state stress amplitude; and

ε_o = steady-state strain amplitude.

The steady-state response of the material is a result of repeated sinusoidal loading. The following equation is used to calculate the steady-state response for stress and strain.

$$f(t) = a + bt + c\cos(wt + f) \tag{2.10}$$

where

> f = stress of strain time history;
>
> ω = angular frequency (radians/s);
>
> ϕ = phase angle (radians); and
>
> a, b, and c = fitting coefficients such that c is the stress or strain amplitude.

Figure 2.5 shows a steady-state response for a stress and strain time histories. The dynamic modulus test described in AASHTO TP-62 is a load-controlled test, therefore the measured response is the deformation. The last five cycles are sampled to measure the amplitude and the phase angle between the stress and strain curves
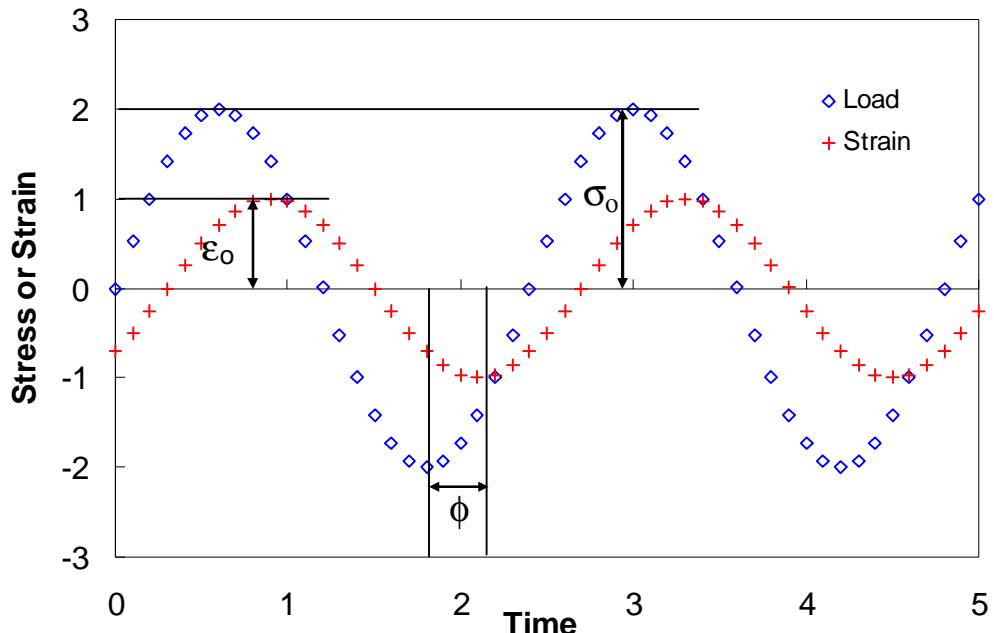

Figure 2.5 Idealized steady-state stress and strain curves with phase angle.

2.1.2 |E*| Using the IDT Test

IDT testing causes a biaxial state of stress in the plane of loading and the plane

perpendicular to it on the face of the specimen. Therefore, determination of |E*| from the

IDT test requires a more complex formulation than uniaxial testing (e.g., AASHTO TP-

62) requires. Drescher et al. (1997) and Zhang et al. (1997) applied the theory of

viscoelasticity to linear elastic solutions, developed by Hondros (1959), to develop linear

viscoelastic solutions for stresses, strains, complex compliances, phase angle, and

Poisson's ratio from the IDT test. The three-dimensional analysis includes calculations

for deviatoric or shear stresses and volumetric stresses and strains (Drescher et al., 1997).

To validate the solutions, the creep compliance from a creep test was used to calculate the

horizontal and vertical displacements from a pulsed loading test, i.e., the MR test. Zhang

et al. (1997) conclude that the viscoelastic solution predicted the displacements

reasonably well; they recommend a further step to validate the solution, which is to test

more replicates at different temperatures.

Kim *et al*. (2004) analyzed the viscoelastic material behavior under sinusoidal loading

in the IDT test with the objective of developing explicit solutions for the |E*|. The

developed solutions were successfully verified by comparing the |E*| values from the

IDT tests against those from the axial compression tests performed in accordance with

the AASHTO TP-62. Twelve asphalt mixtures were used in the verification study.

Equations (2.11) and (2.12) show these solutions for |E*| and Poisson's ratio, ν. The

derivation assumes a plane stress condition, which means that the specimen is thin and,

therefore, the stresses along the thickness direction are zero everywhere in the specimen.

This study furthers the research done by Zhang *et al*. (1997) by predicting the M_R at

multiple temperatures from the |E*| determined by the IDT test. In this study, the |E*| is calculated using the two-dimensional IDT derivation of Kim *et al*. (2004) since the M_R is calculated from two-dimensional elastic analysis.

$$|E*| = -\frac{2P_o}{pad} \frac{b_1 g_2 - b_2 g_1}{g_2 V_o - b_2 U_o} \text{ and} \tag{2.11}$$

$$n = \frac{b_1 U_o - g_1 V_o}{-b_2 U_o + g_2 V_o}, \tag{2.12}$$

where

       P_o = applied load amplitude (N);

       a = loading strip width (m);

       d = thickness of specimen (m);

       V_o = amplitude of sinusoidal vertical displacement (m);

       U_o = amplitude of sinusoidal horizontal displacement (m); and

       β_1, β_2, γ_1, γ_2 = geometric coefficients.

Table 2.1 Geometry Coefficients

IDT |E*|	β_1	β_2	γ_1	γ_2
	-0.0134	-0.0042	0.0037	0.0116
M_R	k_3	K_4	k_1	k_2
	-0.00067	0.000209	-0.00018	0.000578

The coefficients in Equations (2.11) and (2.12) are listed in Table 2.1. These coefficients are based on a 152.4 mm (6.0 in.) diameter specimen with a 50.8 mm (2.0 in.) gauge length, which are the geometries used in this study. The sign convention for load, strains, and displacements is positive for tension and negative for compression.

Therefore, in the IDT test, horizontal displacements are positive while vertical displacements and compressive loads are negative.

2.2 Resilient Modulus (M_R)

M_R can be calculated by several different methods, including the ASTM D 4123-82, the NCHRP 1-28 method , the SHRP P07 protocol, AASHTO TP-31 standard, or the Roque and Buttlar equation (1992), which accounts for the bulging effects of the specimen. The NCHRP 1-28 elastic solutions are used in this paper. The equations for calculating M_R and Poisson's ratio are given as follows:

$$M_R = \frac{P}{Ud}(k_1 - k_2 n) \quad \text{and} \tag{2.13}$$

$$n = \frac{k_3 + k_1(V/U)}{k_4 + k_2(V/U)}, \tag{2.14}$$

where

M_R = resilient modulus (MPa);

P = applied load (N);

d = thickness of specimen (m);

U = recoverable horizontal displacement (m);

V = recoverable vertical displacement (m); and

k_1, k_2, k_3, k_4 = constants.

Equations (2.13) and (2.14) can be combined to yield the following relationship:

$$M_R = \frac{P}{Ud}\left[k_1 - k_2 \frac{k_3 + k_1(V/U)}{k_4 + k_2(V/U)}\right]. \tag{2.15}$$

These equations are based on the linear elastic solutions, developed by Hondros (1959), after accounting for the non-uniform stress and strain distributions in the IDT specimen, shown in Figure 2.6. The constants in Equations (2.13) and (2.14) are listed in Table 2.1. Note that these constants are different from the constants for $|E^*|$, because the coefficients for M_R are derived using linear elastic theory whereas those for $|E^*|$ are derived using linear viscoelastic theory.
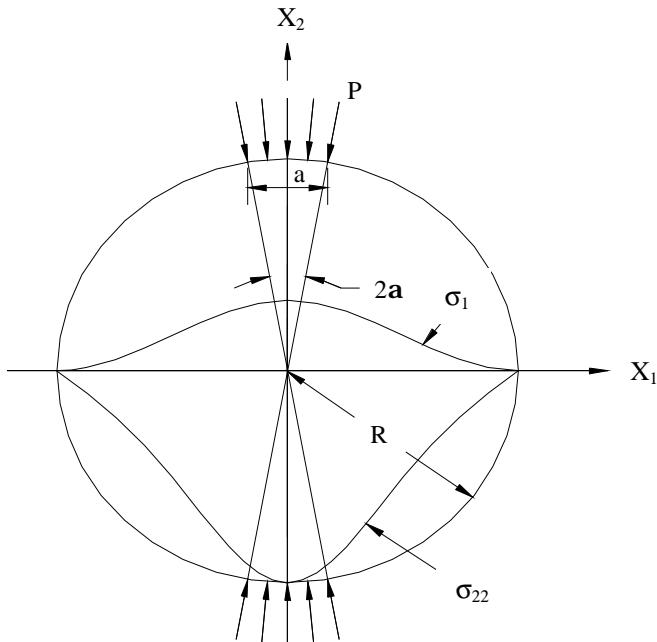

Figure 2.6 Stress distribution in the IDT specimen subjected to a strip load.

CHAPTER 3   MATERIALS AND SPECIMEN FABRICATION

The specimens in this study comprise ten different mixtures listed in Table 3.1. Five of these mixtures, S12.5C, S12.5CM, S12.5FE, S12.5F and B25.0C, have been provided by the North Carolina Department of Transportation. The first mixture is a surface mixture that has a 12.5 mm (0.5 in.) nominal maximum aggregate size (S12.5C) and coarse aggregate gradation. The granite aggregate came from a quarry in eastern Alamance County, North Carolina. The B25.0C mixture is a 25.0 mm (1 in.) nominal maximum

aggregate base mixture designed with the same aggregate and binder as S12.5C. The S12.5FE mixture was designed to match the gradation of the S12.5C but used a slate aggregate obtained from Asheboro, North Carolina. The main difference is that the slate aggregate contains a large percentage (7.7%) of the aggregate characterized as flat and elongated (S12.5FE) compared to 2.7% for the S12.5C mixture. Based on the large percentage of flat and elongated particles in the S12.5FE mixture, it is assumed that this mixture has a larger degree of anisotropy than the more cubical reference mixture (*e.g.* S12.5C). The S12.5F mixture was a fine mixture with a large percentage (47%) by weight of aggregate of fines. The S12.5CM mixture has same gradation as S12.5C but uses a SBS modified binder with a PG grade of 76-22 from Citgo Savannah. The other five mixtures were used to evaluate systemic volumetric variations. In these cases, the reference mixture for this project, S12.5C, was adjusted to add or subtract air void (AV) or asphalt content (AC).

Table 3.1 Summary of Asphalt Mixtures

Mix	% AV	% AC	Asphalt Grade	NMSA	Gradation
S12.5C	4	5.5	PG 64-22	12.5 mm	Coarse
S12.5C-AV+2	6				
S12.5C-AV-2	2				
S12.5C-AC+1	4	6.5			
S12.5C-AC-1	4	4.5			
S12.5CM	4	5.5	PG 76-22		
S12.5FE	4	5.7	PG 64-22		
S12.5FE-AV+3	7				
S12.5F	4	4.8			Fine
B25.0C	4	4.9		25.0 mm	Coarse

The target air voids for most of the mixtures was 4% ± 0.5%. The binder for all mixtures, except S12.5CM, is a PG 64-22 acquired from Citgo in Wilmington, North Carolina. The mixing temperature is 158°C (316°F) and the compaction temperature is 145°C (293°F). The S12.5CM uses a SBS-modified binder with a PG grade of 76-22 from Citgo in Savannah. The mixing and compaction temperatures are the same as those of the other binder.

An important component of this study is the evaluation of different compaction methods, as seen in Table 5.1. For a majority of the specimens, the mixtures were compacted using the SGC. Three different specimen geometries were produced using the SGC: cylindrical specimens according to AASHTO TP-62 specifications (axial), prismatic column specimens (prism), and short cylinders for IDT testing. The initial specimen geometries were cut to the final dimensions listed in Table 5.1. The prism dimension of 70 mm corresponds to a side of a square that has a diagonal of 100 mm. The diagonal length was chosen to eliminate the need to produce or modify metal endplates for 100 mm diameter axial specimens. This decision is important for acceptance by practitioners because equipment such as the Simple Performance Tester (SPT) are readily available. Also, the thickness allows the specimen to be easily removed from a 100 mm (4.0 in.) layer, which is a typical thickness for thin pavements. Two IDT specimens, each with a diameter of 150 mm and a thickness of 38 mm (1.5 in.), were cut from the initial specimen. The thickness of the specimens was selected to balance the need for 1) a thin specimen to meet the plane stress assumption in the viscoelastic |E*| solutions and 2) a RVE in the diametral direction needed to test mixtures with large

aggregates. Roque and Buttlar (1992) suggest 25 mm as the ideal thickness of IDT specimens based on three-dimensional finite element analysis. However, 25 mm is not thick enough to meet the conventionally accepted RVE requirement of the minimum dimension to maximum aggregate size ratio of three for even 12.5 mm mixes. 38 mm is higher than the ideal thickness necessary to satisfy the plane stress condition, but was selected in this study based on the consideration of the RVE requirement.

The other compaction procedure was to compact a slab to reproduce the field environment. The mold was a steel frame with the dimensions of 61 by 60 cm placed on top of a sheet of plywood covered with a ¼ in. sheet of aluminum. The mold was divided into six sections in order to extract one IDT and prism sample from each section. The compactor was a steel wheel compactor with a vibratory rear wheel.

Several differences exist between the slab produced by the steel wheel compactor and the standard method (AASHTO T 312) of preparing and compacting a specimen using the SGC. To produce a large quantity of mixture (≈ 100 kg) for a slab, the mixture was divided into smaller equal batches of approximately 6.5 kg for production. Each batch was aged for 4 hours at 135°C (275°F) and combined into 8 pans of specific masses. After mixing, the slab materials were cooled and stored in pans covered with aluminum foil and plastic wrap to reduce further aging. Once enough mixture was produced, the 8 pans were heated from room temperature to the compaction temperature (149°C) for 3 hours. The S12.5FE mixture was compacted a few days after mixing, whereas the S12.5C mixture was stored in sealed pans for almost two months before compaction.

To prepare for compaction, the mold was placed inside the building to reduce environmental effects such as the intensity of the sun and the temperature. The first layer was placed in the cool mold by pouring the material into the pre-marked quadrants. After pouring the mixture into the mold, a hand rake was vigorously worked into the mixture to settle and level the mixture. Compaction began immediately after mixture placement. The first layer was lightly compacted to stabilize the structure and prevent shoving. While the top layer was scarified to produce a continuous layer, the second layer mold and ramps were added to compact the second layer. The second layer was placed like the first layer while the first layer was still hot (> 100°C). The first and second lift heights were both 5 cm (about 2.0 in.). The total structure height after placing the second lift was 10 cm (about 4.0 in.). Due to the difficulty in compacting a thick, continuous layer, the air voids of the slabs were not equal to 4%. The S12.5C and S12.5FE slabs had samples with 6% and 7% air voids, respectively.

CHAPTER 4   TESTING PROGRAM

4.1 Geometry Comparisons

The testing procedure for the axial and prism specimens was similar, but slightly different from the IDT |E*| testing. In both cases, loose-core type LVDTs were mounted to the specimen surface to record specimen deformations. The LVDTs for the axial specimens were placed 90° apart from each other. For the prism specimens, the LVDTs were placed at the center of each face. Both axial and prism specimens had a gauge length of 100 mm (about 4.0 in.). Measurements of both horizontal and vertical deformations were taken on the front and back faces of the IDT test specimens. Two LVDTs were mounted on the

front surface, one vertically in the plane of the center of the loading strip and one rotated

90° from the vertical plane at a gauge length of 50.8 mm (2.0 in.). The same set-up was

repeated on the back of the specimen but with the position of the horizontal LVDT

flipped 180° so that both horizontal wires extended from the specimen on the same side,

as seen in Figure 4.1.

The other difference between the two tests is the difference in loading device. Testing

the axial and prism specimens requires contacting the loading plates and applying

sinusoidal loading up to 25 Hz. IDT testing requires a device to hold the specimen and

apply strip loading. Once the specimen has been prepared, the specimen is placed in the

Load Guide Device (LGD), developed from the Strategic Highway Research Program

(SHRP). The NCHRP 1-28 study recommends using the SHRP LGD because its two

columns provide stability to prevent the specimen from rocking without causing

significant friction between the guide posts and the upper loading plate (Barksdale *et al.*,

1997). The first step of the set-up procedure is to align the rod to prevent unequal loading

of the front versus the back. Experience showed that allowing the rod to align itself while

applying a load to an aluminum specimen was the best solution. A centering device was

used to ensure consistent results in the alignment of the specimens with the loading strips.

(a)

(b)
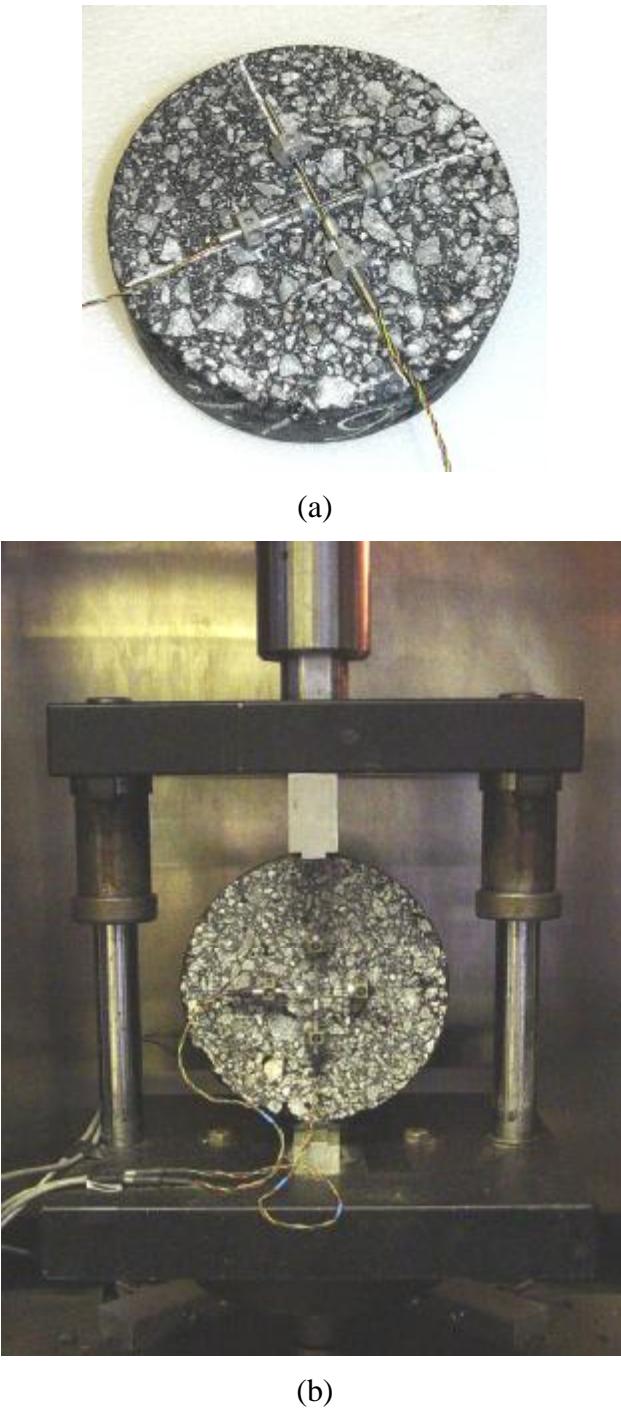

Figure 4.1 (a) Surface-mounted LVDTs and (b) IDT test setup with SHRP LGD.

The testing was carried out using a closed-loop servo-hydraulic machine with a 25 kN

(5.62 kip) load cell. A temperature chamber with refrigeration and heat was used to

control the temperature during the tests. A dummy asphalt concrete specimen with the same dimensions as the test specimens was used to monitor the temperature of the test specimens. The loading histories for the |E*| of all tests consisted of eight frequencies (25, 10, 5, 1, 0.5, 0.1, 0.05, 0.01 Hz) at three temperatures (-10, 10, and 35°C). Axial and prism specimens were also tested at the first six frequencies at 54°C. IDT testing did not include this temperature due to increased punching shear under the loading strip. The load levels were adjusted to keep the strains below 75 microstrains for the axial and prism specimens. In the IDT |E*| test, the target for horizontal strains was 30 microstrains which resulted in 60 to 100 microstrains vertical strains depending upon the temperature and Poisson's ratio. It is important to note that the strain levels chosen to limit the material to a linear viscoelastic response are based on experience. Other studies have tested specimens at higher strain levels, which might produce different results.

4.2 Comparison Between |E*| and M_R

IDT |E*| testing and IDT M_R testing were both conducted following the same set-up procedure. The difference between the two tests is the difference in loading sequence and temperatures. The loading histories for the |E*| and M_R tests are summarized in Table 4.1. Testing the |E*| at different temperatures than the M_R demonstrates the strength of time-temperature superposition. It is noted that the recommended gauge length used for acquiring the deformations is varies standard to standard. Therefore, the geometry constants in the |E*| and M_R equations must be recalculated for the gauge length that is specified in each standard.

Table 4.1 Comparison of Loading Histories for IDT $|E^*|$ and M_R

Test Type	Test Temperatures (^{o}C)	Loading History	Frequency (Hz)
$|E^*|$	-10, 10, 35	Sinusoidal	25, 10, 5, 1, 0.5, 0.1, 0.05, 0.01
M_R	5, 25, 40	Haversine Pulse	10 Hz (0.1s) Pulse, 0.9 s rest period

In the IDT $|E^*|$ test, the load amplitude used at the beginning of this research was adjusted to target 60 to 80 microstrains in the horizontal direction (i.e., ε_{11}) of the center of the specimen. However, this load resulted in a large vertical displacement, which caused a slight shear deformation under the loading strip. Therefore, the load level was reduced to induce 60 to 100 microstrains in the vertical direction (i.e., ε_{22}) of the center of the specimen. This reduced load level, however, yielded a smaller horizontal strain and a lower signal-to-noise ratio that made the analysis more difficult. It is interesting to note that the resulting $|E^*|$ mastercurves obtained from these two different load levels are not statistically different. In the IDT M_R test, the load levels that yield vertical strains between 60 to 80 microstrains were used.

The data were acquired using LabVIEW software and a National Instruments board. The data acquisition rate was one thousand points per second. The rate was chosen to have 100 points for the 0.1 second haversine pulse in M_R testing.

CHAPTER 5   MEASURING DYNAMIC MODULUS WITH DIFFERENT GEOMETRIESEQUATION CHAPTER (NEXT) SECTION 1

5.1 Method

To evaluate the challenges set out in the Introduction, several comparisons are necessary to account for interaction effects. The questions to answer are:

1. Do IDT and axial testing procedures produce the same |E*| mastercurve?

2. What is the magnitude of anisotropic effects?

3. What are the geometry influences for prism versus axial specimens?

4. What are the differences in IDT |E*| measured from SGC versus slab specimens?

5. Do the non-uniform stress and strain fields in IDT testing influence the measured |E*| values?

6. Are prism and IDT specimens of adequate size to test large aggreage mixtures?

Table 5.1 provides an overview of the mixtures, geometries, and compaction methods used in this study for the comparisons.

Table 5.1 Summary of Completed Test and Specimen Fabrication Methods

	Test Type				
	Axial Compression |E*|			IDT |E*|	
Test Specimen Geometry	Cylinder	Prismatic Column		Disk	
Specimen Type	Axial	Prism		IDT	
Original Specimen Geometry	Cylinder	Cylinder	Slab	Cylinder	Slab
Original Specimen Dimensions	150 mm diameter, 178 mm height		600 mm by 600 mm by 100 mm	150 mm diameter, 120 mm thickness	600 mm by 600 mm by 100 mm
Specimen Final Dimensions	100 mm diameter, 150 mm height	70 mm length, 70 mm width, 150 mm height		150 mm diameter, 38 mm thickness

Mixture types described in Table 3.1

5.2 Discussion of Results

Several comparisons mentioned earlier are necessary to determine if IDT and prism specimens are acceptable alternatives to the standard axial specimen. The evaluations are categorized as: 1) geometry, 2) non-uniform stresses and strains, 3) anisotropy, and 4) representative volume element (RVE). Throughout this section, the labels of each specimen and geometry type are represented by two letters. The first letter represents the compaction method, i.e., (S)GC and (R)olling-wheel; and the second letter represents the geometry, i.e., (A)xial, (P)rism, and (I)DT.

Theoretically, testing specimens with different geometries should produce the same values, provided the material is tested in the range of linear viscoelastic behavior and has the appropriate RVE. The study by Kim et al. (2004) presents a comparison of IDT and axial mastercurves. The conclusion is that IDT and axial geometries produce similar mastercurves a majority of the time. Therefore, the expected outcome of this study is a similarity between the mastercurves generated by the two different geometries.

Due to the specimen-to-specimen variability, statistical methods are used to determine if the mixtures are similar or different. The statistical test chosen for the comparison is the equal variance two-tailed paired t-test. The null hypothesis is that the axial and IDT mastercurves are the same. The test is performed at six testing conditions, (10 and 0.1 Hz at -10, 10, and 35°C), to evaluate different regions of the curve. These frequencies are denoted as fq1 – fq6, representing 0.1 Hz at 35°C to 10 Hz at -10°C (*i.e*., smallest to largest reduced frequency). The data were generated by fitting the measured data for each

replicate with a sigmoidal curve based on a shift factor curve referenced to 10°C. Then, the |E*| values for the six frequncies were predicted using the conditions above.

One problem with using multiple t-tests to evaluate data is an increased probability of finding significance when significance does not exist or finding Type I error in the statistics. Therefore, the data were evaluated using a multiple test p-value adjustment method, which helps adjust the p-values of the t-test for Type I errors. The method used in this study is the stepdown bootstrap method. This method involves generating a pseudo data set by sampling from the input data. The dataset is evaluated using the paired t-test. These steps are repeated many times to generate a population of comparisons. The adjusted p-value is the proportion of the population of comparisons that is less than or equal to the original p-values (SAS Institute, 2004). Of the multiple test methods, this stepdown bootstrap method is most likely to show significance, indicating a difference between sample groups. One challenge with using this method is that it determines significance based on the pooled variances of all the inputs. Some comparisons involve one set of data with low variability at one frequency and high variability at another frequency, such as seen in Figure 5.1 and Figure 5.2. These graphs allow observations of the variability of the data, and any difference between IDT and axial values. Overall, the variability is similar between geometries except for a few cases such as S12.5FE IDT (Figure 5.2b). This difference means that some p-values would be more precise than others.
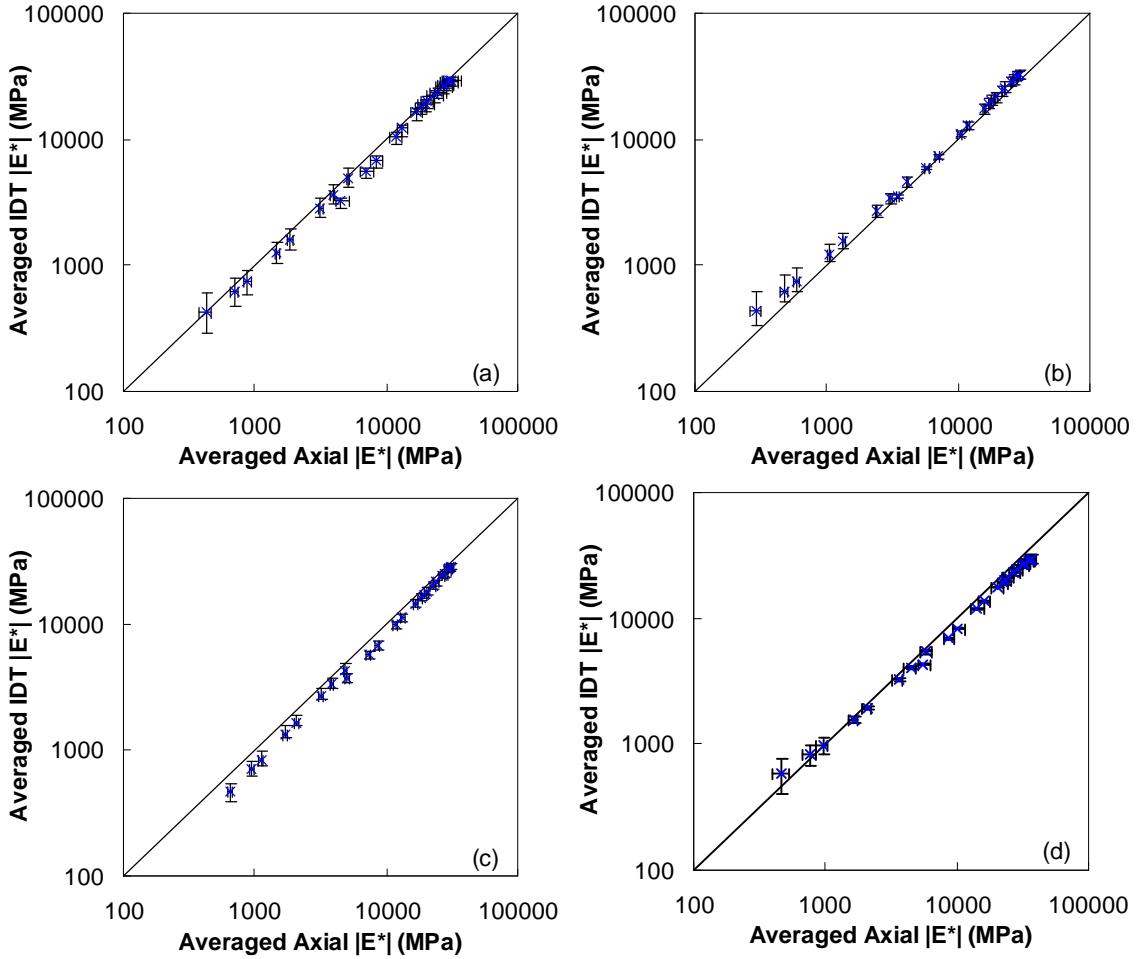

Figure 5.1 Log-log line-of-equality of SA and SI |E*| values for (a) S12.5C, (b) S12.5FE, (c) S12.5CM, and (d) S12.5C-AV-2.

To compensate for this effect, the standard deviation was determined for each frequency.

The standard devations from each mixture for a given specimen geometry were averaged.

The assumption is a given testing method has a normal variability. Sometimes the

variability between replicates is small, other times it is large, but the variability of the test

method should not change. The statistical tests were performed on the averaged value

plus/minus one averaged standard deviation. The standard deviation was largest to

smallest: axial, IDT, prism. The averaged standard deviation is approximately a 15%

deviation from the average. The following discussion focuses mainly on whether a

statistically significant difference exists between the methods. Graphical comparisons are

presented to support the statistical results.
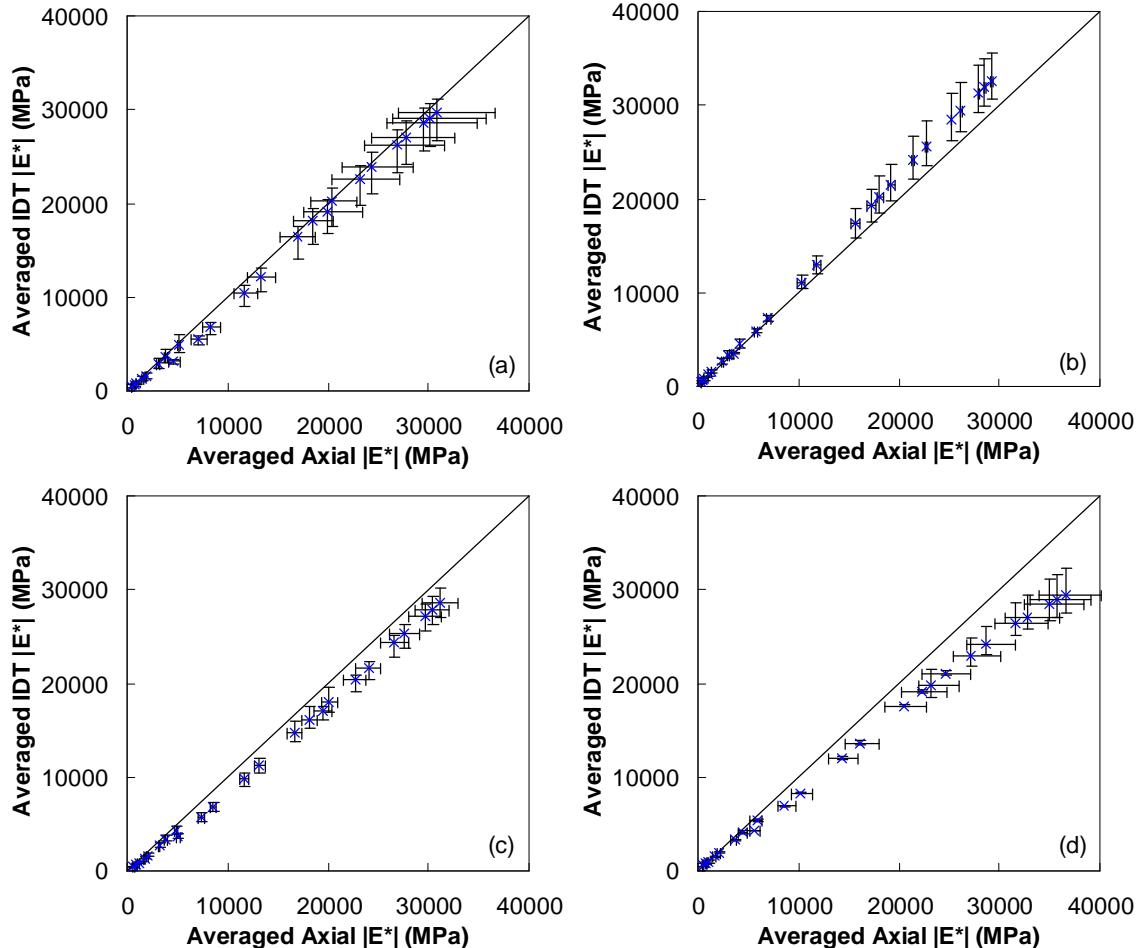

Figure 5.2 Line-of-equality of SA and SI |E*| values for (a) S12.5C, (b) S12.5FE, (c)
S12.5CM, and (d) S12.5C-AV-2.

Figure 5.1 and Figure 5.2 provide evidence that axial compression and IDT

measurements produce similar |E*| values. In these graphs, note that the data series

represents the averaged values. Since data points were not measured at exactly the same

temperature, the points are the average of linearly interpolation from the different

reduced frequencies corresponding to the measured temperatures. The error bars

represent the maximum and minimum |E*| values from these replicates. The number of

replicates used is shown in Table 5.1.

5.2.1 Geometry Comparisons

Table 5.2 Statistical Results for Geometry Comparisons

Evaluation	Comparison	Mixture	Stepdown Bootstrap p-value					
			fq1	fq2	fq3	fq4	fq5	fq6

IDT versus Axial

Table 5.2 shows the p-values from t-tests comparing IDT and axial values for different

mixtures. Overall, most p-values show no statistical difference. From this table it is

observed that the S12.5C, S12.5FE, S12.5F, and B25.0C mixtures show no significant

difference between IDT and axial mastercurves. B25.0C is significant at high temperature

and low frequency. The IDT |E*| value is higher than axial, which is expected. At high

temperatures, the material is soft and easily deforms. In IDT testing the RVE is small

(*e.g.*, 2), therefore any large particle could reduce the deformations over the gauge length,

which increase the |E*| value. The general finding from these particular mixtures is

important because they cover a range in mixture types and provide evidence that IDT

testing is suitable for a wide range of mixtures. Measurements with the S12.5CM mixture show statistical insignificance at low reduced frequencies (fq1-fq4). Also of note is the S12.5-AV-2 mixture, where the results show p-values near the 0.05 threshold, except for fq2. A closer analysis of these results suggests that the data from IDT and axial compression are indeed different. The reason fq2 for S12.5-AV-2 is highly insignificant is the IDT curve crosses the axial curve at this point. This is an undesirable result because it indicates that the shapes of the curves are different. Even though some mixtures show a significant difference, most of the mixtures show insignificance. Based on statistical information, IDT and axial mastercurves are concluded to be similar.

Axial versus Prism

Another geometry comparison of interest is that of axial and prismatic specimens. It is expected that prismatic and axial specimens should be similar because the compaction and loading directions and state of stress are the same as for axial specimens. The only difference is a smaller cross-sectional area in prismatic specimens to apply the load.

The data in Table 5.2 show that comparisons between prism and axial specimens have no statistically significant difference. The variability of prism testing is the smallest of all three geometries. The average variability of the data points is approximately 10% of the averaged $|E^*|$ value. Based on this evidence, comparisons between prism and IDT specimens can be considered similar to comparisons between axial and IDT specimens.

RVE

While evaluating different geometries for measuring the $|E^*|$, it is important to consider the possible limitations of each geometry. The RVE comparison in Table 5.3 shows that

the difference between axial, IDT, and prism specimens is statistically insignificant for all frequencies except for the previously mentioned small reduced frequency in the SA versus SI comparison. Given the large aggregate size, and the small RVE ($\approx$ 2), this observation provides evidence that the IDT gauge length of 2 inches and the thickness of 1.5 inch are adequate to capture the response of the mixture. Kim *et al.* (2004) show an increase in the difference between axial and IDT specimens for increasing nominal maximum size of aggregate (NMSA) values, but this study shows a similarity. Caution should be exercised when comparing IDT and axial mastercurves at low reduced frequencies. Large variability occurs in this region. This variability is to be expected because the lower |E*| value corresponds to 35°C, the temperature at which the material is rather soft and the large aggregate would disproportionately affect the deformation over the gauge length (i.e., larger stiffness gradient between constituent phases).

Table 5.3 Statistical Results for RVE and Non-uniform Stress

Evaluation	Comparison	Mixture	Stepdown Bootstrap p-value					
			fq1	fq2	fq3	fq4	fq5	fq6
RVE	SA vs SI	S12.5C	0.60	0.83	0.20	0.81	0.92	0.69
		B25.0C	0.03	0.11	0.54	0.92	0.74	0.45
	SA vs SP	S12.5C	0.92	0.59	0.92	0.15	0.23	0.74
		B25.0C	0.17	0.85	0.92	0.87	0.84	0.57
Non-uniform stress	RP vs RI	S12.5-AV+2	0.62	0.88	0.07	0.07	0.07	0.07
		S12.5FE-AV+3	0.09	0.04	0.92	0.47	0.14	0.15

5.2.2 Non-uniform State of Stress

An important comparison between IDT and axial mastercurves is seen in evaluating the effects of the different states of stress. As discussed previously, only the specimens obtained from the compacted slabs may be used to fairly assess this factor. Table 5.3 shows the results that demonstrate non-uniform state of stress does not produce a

significant difference. In the case of the S12.5C-AV+2 mixture, a nearly significant

difference is observed. Significance is seen in the S12.5FE-AV+3 mixture at low reduced

frequencies. IDT testing at low reduced frequencies is more variable due to the high

strain levels and damage to the specimen at high temperatures. To gain further insight

into these observations, Figure 5.3 illustrates the results of the testing in both semi-log

and log-log space for the two mixtures.
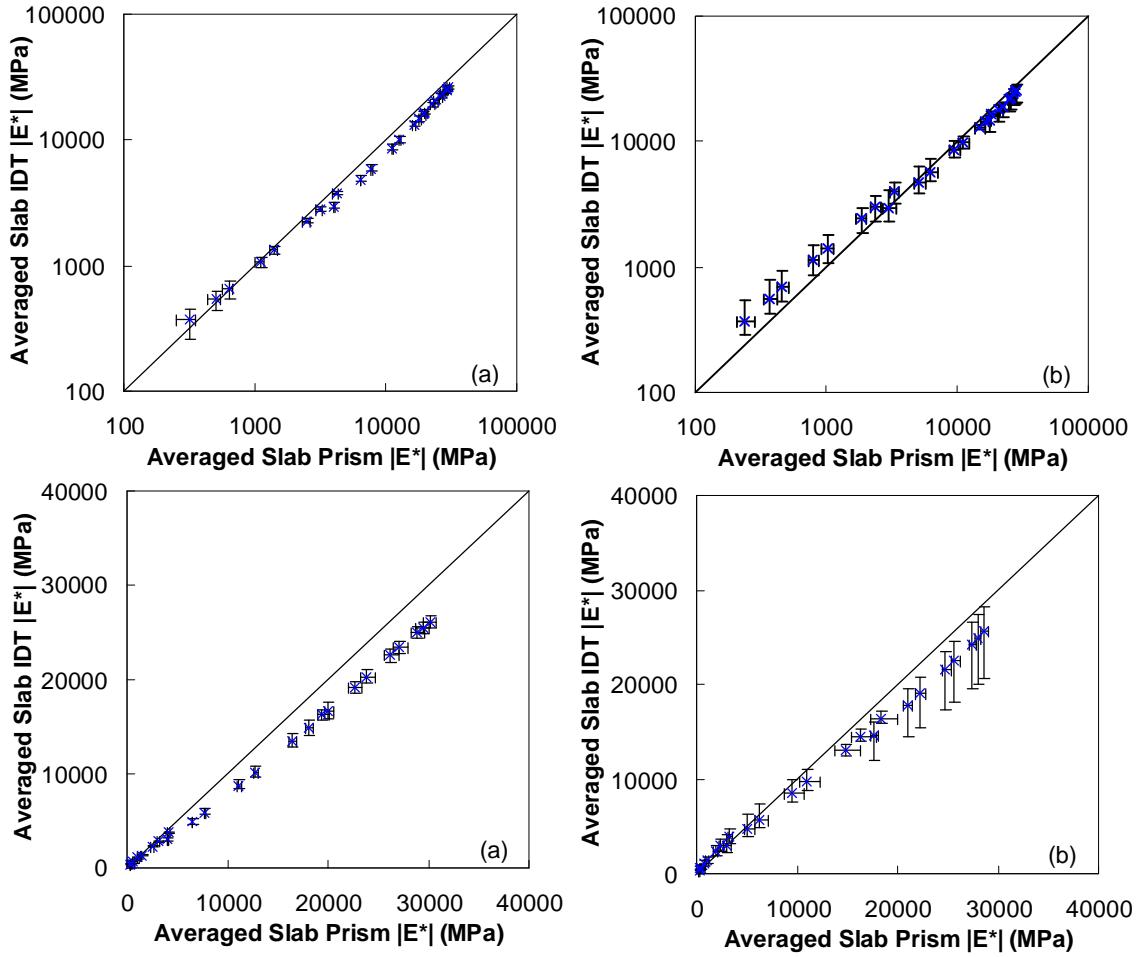

Figure 5.3 Line-of-equality of RI and RP |E*| values for (a) S12.5C-AV+2 and (b) S12.5FE-AV+3.

In Figure 5.3, for the S12.5C-AV+2 mixture, the RI mastercurve is lower than the RP

mastercurve except at the lowest modulus value. For the S12.5FE mixture, the RP and RI

mastercurves are similar except in the lower modulus range (i.e., low reduced

frequencies). Once again, the inconsistency in variability for the same geometry is

shown, though in this case the RI specimens tend to have larger variability than RP

specimens do. Recall that the S12.5C-AV+2 mixture contains cubical aggregates, which

research suggests should result in less inherent anisotropy than mixtures with flat and

elongated aggregate (Saadeh, 2002). It is, therefore, unexpected that this mixture shows

more significance with regard to stress state than the S12.5FE-AV+3 mix, so it is

assumed the state of stress does not cause the difference shown. The conclusion is the

state of stress does not effect the |E*| values due to the stastical analysis.

5.2.3 Anisotropy

Anisotropy is a difficult parameter to quantify. It is potentially influenced by compaction

and loading direction as well as the physical characteristics of the aggregate particles. In

this study, the comparison is further complicated due to differences in air voids and aging

that were present both between mixes and between the different test configurations within

mixtures. A statistical comparison of the air voids was performed to determine if the

effect of air voids is significant. The difference in air voids is statistically insignificant for

axial and IDT geometries and S12.5C and S12.5FE mixtures over the tested range (2 –

7%). Other studies have made similar observations for air voids in this range (Kim *et al.*,

2005, Mirza *et al*., 2006). Based on this conclusion, the effect of air voids was shown to

be insignificant; however, the interaction between air voids and other factors may not be

insignificant. By collating the information in Table 5.1 and Table 3.1 with the necessary

comparisons from Table 5.3, the challenges of interpreting the data with differences in aging and air voids is observed.

Both compaction and anisotropy comparisons have aging effects and differences in air voids, which are inconsistent. For example, for comparisons of anisotropic effects, each comparison for the S12.5C-AV+2 mixture can be made with the same air voids, but the comparisons for the S12.5FE mixture require data with air voids of 4% (SA) and 7% (RP and RI). In addition, both mixtures contain aging effects due to differences in fabrication. The slab mixture was cooled and reheated instead of immediately proceeding to compaction like the SGC specimens. The greater aging of the rolling-wheel specimens should produce a higher stiffness. Therefore, the aging effect may account for the smaller distance to the line-of-equality because the S12.5C mixture sat in pans for two months instead of a few days. The difference in aging alone, though, does not explain the reason that the SI and SP mastercurves are higher than those of the RI and RP. Therefore, it should be understood that the following conclusions are drawn with less confidence than if the materials had the same air voids and if there had been no aging effects.

SGC versus Field Compaction

Rehabilitation design requires forensic work and field specimens for testing. The mechanistic-empirical models in the MEPDG software are based on laboratory data. Therefore, it is important to know if any difference exists between the material property measured from laboratory specimens and specimens acquired from the field. In this study, both prism and IDT samples were removed from a slab to simulate field samples.

To compare the effects of compaction on anisotropy, comparisons should be made between the SI and RI. The results in Table 5.4 show the difference in S12.5C is insignificant, but in S12.5FE is significant. It is important to note that the rolling-wheel specimens have higher air voids than the SGC specimens, which could be the source of the difference. But as previously mentioned, air voids showed no statistical difference. Because the effects of compaction based on IDT were inconclusive, a comparison was made with prism specimens (SP vs. RP). This comparison removes any interaction effects from the different states of stress. The results of this comparison show that the difference between mastercurves is significant for the S12.5C. The reason for the difference is the smaller standard deviation used to prism specimens than IDT or axial. If the standard deviation for the IDT testing had been used, the mixture would have no statistical difference.

Table 5.4 Statistical Results for Compaction and Anisotropy

Evaluation	Comparison	Mixture	Stepdown Bootstrap p-value					
			fq1	fq2	fq3	fq4	fq5	fq6
SGC vs Field Compaction [b]	SI vs RI	S12.5-AV+2 [a]	0.17	0.07	0.17	0.27	0.165	0.17
		S12.5FE [a]	0.20	0.81	0.17	0.04	0.04	0.066
	SP vs RP	S12.5-AV+2	0.008	0.008	0.008	0.008	0.041	0.065

		S12.5FE [a]	0.40	0.45	0.27	0.19	0.17	0.19

Note: [a]air void difference   * Compaction (first letter): (S)GC or (R)olling Wheel

[b]aging difference   Geometry (second letter): (A)xial, (P)rism, or (I)DT

Because previously mentioned difficulties complicate a definitive conclusion regarding compaction method, it is beneficial to examine the possible sources of differences

between the comparisons. The known differences between the two curves, SI and RI, are the method of compaction and the aging. Only the aging condition is inconsistent between the mix types. As previously mentioned, the effect of aging does not entirely account for the SGC specimens being stiffer than the rolling-wheel specimens. Even though the statistics reveal insignificant influence from the compaction method, a numerical investigation seems to suggest an increase in $|E*|$ values from the SGC. The increase may be a result of the air distribution within a gyratory specimen, since the center of the specimen is known to be denser in the center where the LVDT's measure deformations than the outside, which could increase the $|E*|$ values. Based on statistics, the values are not different.

Effect of Anisotropy on Field to Laboratory Values

To evaluate the magnitude of the effect of anisotropy, Table 5.4 displays results that show, in general, the effects are insignificant. However, the S12.5FE rolling-wheel specimens had 7% air voids. Due to the limitations of materials, axial specimens had 4% air voids. Therefore, comparisons are made based on the assumption that air voids do not produce different $|E*|$ values. The comparison between SA and RP shows an insignificant difference, providing further evidence that prism and axial specimens produce the same results. This result implies that compaction does not create a significant difference because previous evidence suggests that measurements from axial and prism specimens produce the same $|E*|$ mastercurves. Recall that the comparisons between SA and SI specimens show, in general, insignificant statistical difference. Because compaction may not significantly affect the mastercurves, these results imply that the differences in

compaction and stress-strain analysis do not have an effect. In the comparison of SA and RI, a significant difference occurs at high reduced frequencies or at high modulus values. In the S12.5C-AV+2 mixture, the SA values are higher than S12.5C, which is unexpected since S12.5-AV+2 has greater air voids and is less dense, the |E*| values should remain the same or decrease. This difference could explain why S12.5C-AV+2 is different but S12.5FE is not. The results seem to imply that the magnitude of anisotropy is not as great a factor as might be expected. Because the material's property is measured at low strain levels, which generally does not mobilize the aggregate, this conclusion is reasonable. Results suggest that the compaction direction and stress-strain analysis generally do not have an effect.

5.3 Conclusions

Based on the results presented in this chapter, the following conclusions can be drawn:

1. The statistical difference between IDT and axial specimens is insignificant for a variety of mixture gradations at low strain levels.

2. Sources of anisotropy and its effects are difficult to isolate. Based on the data, compaction and loading direction have an insignificant effect.

3. Prism specimens provide a good alternative for axial specimens in forensic work. Prisms have statistically similar |E*| values for SGC and rolling-wheel specimens.

4. The effects of non-uniform stress in IDT testing is insignificant compared to prism specimens.

5. The prism and IDT geometries provide an adequate alternative for measuring the |E*| for asphalt concrete mixtures with NMSA up to at least 25.0 mm. The IDT

test method has a small RVE, which is adequate except at small reduced

frequencies (high temperatures and long loading times), due to the gauge length.

6. The alternative geometries explored in this study appear to reduce the specimen-
to-specimen variability.

Based on these conclusions and the observations in this chapter, the |E*| can be acquired

through several geometries with minimal concerns about differences stemming from the

RVE, non-uniform states of stress, and anisotropy.

CHAPTER 6   PREDICTING DYNAMIC MODULUS FROM RESILIENT MODULUS USING AN ARTIFICAL NEURAL NETWORK

6.1 Method

This study has three stages for investigating whether M_R data can be used to predict the

|E*| using the ANN: 1) developing a database with corresponding |E*| and M_R values; 2)

training the ANN; and 3) verifying the accuracy of the predictions.

Developing a database with |E*| and M_R values can be a lengthy task if the properties

are measured in the laboratory, especially for a database comprehensive enough to

encompass a large range of mixture variables, such as binders, gradations, NMSA, voids

in mineral aggregate, voids filled with asphalt, air voids, etc. The proposed method is to

use a comprehensive |E*| database, and then populate the database with M_R values using

the method presented.

As previously mentioned, several M_R formulations exist. The M_R solution used in this

study is the NCHRP 1-28 (Barksdale *et al.*, 1997) elastic formulation, shown in Equation

(6.1).

$$M_R = \frac{P}{Ud}(k_1 - k_2 n),$$ (6.1)

where

M_R = resilient modulus (MPa);

P = applied load (N);

U = recoverable horizontal displacement (m);

d = thickness of specimen (m);

ν = Poisson's ratio; and

k_1, k_2 = (-0.00018, 0.000578).

The unknowns in the equation are the load, the horizontal displacement, and the Poisson's ratio. The Poisson's ratio is assumed to be constant for a given temperature (0.2, 0.35, and 0.45 for 5°, 25°, and 40°C, respectively). To determine the horizontal displacement amplitude, a two-dimensional viscoelastic formulation is needed to predict a strain history from a given loading history for a biaxial state of the stress. Equation (6.2) shows the formulation for calculating the horizontal strains needed for Equation (6.1). Equation (6.2) is based on the generalized Hooke's Law in conjunction with the viscoelastic correspondence principle and the plane stress formulations of Hondros (1959):

$$U = \frac{2(g_1 + n g_2)}{pad} \int_0^t D(t-t) \frac{\partial P}{\partial t} dt,$$ (6.2)

where

D = compliance

a = loading strip width (m);

d = thickness of specimen (m); and

γ_1, γ_2 = geometric coefficients for a gauge length of 50.8 mm (0.0037, 0.0116).

To predict the horizontal displacement, a representative loading history (*i.e.* a repeated 0.1 second haversine pulse followed by a 0.9 second rest period) is introduced to Equation (6.2). Once the horizontal strains are calculated, the M_R can be calculated by using Equation(6.1).

After the database has been populated, the next step is to train the ANN. The ANN is a model composed of nonlinear transfer functions, typically a sigmoidal function, between inputs and outputs. The ANN is trained using the feedfoward, backpropagation method. The feedforward portion of the training involves presenting the inputs and the desired outputs (targets) so that the computer program can make the appropriate connections with the transfer functions. The backpropagation portion involves predicting the output using a given input, which is the ultimate purpose of the ANN. The program evaluates the error between the targeted and predicted outputs based on the weighted transfer functions. Using the Levenberg-Marquardt optimization algorithm, the computer selects new weighted values and repeats this process until the program reaches a maximum number of iterations or the minimum error desired. Further information regarding the use of neural networks in pavement applications can be found in Xu *et al.* (2002).

Once the network has been trained, the next process is to verify the accuracy of the network. Some trained networks may show small errors between targeted values given for the feedforward method and predicted values used in training, but may not have the predictive capabilities desired when new data are presented to it. Some data from the training dataset are reserved for use as verification of the predictions after training. In training the ANN, the user selects how many degrees of freedom the network has to fit

the data. If the network has too many degrees of freedom, the data can predict the training

data well, but may not be able to interpolate for new inputs, which is the ultimate purpose

of training the network.

In order to verify the accuracy of the predictions, an independent database containing

both measured $|E^*|$ and M_R values is used. The measured $|E^*|$ values allow for a

comparison between predicted and measured values. The M_R data are necessary to

determine if the greater variability in measured M_R affects the ANN results.

6.2 Theoretical Background

6.2.1 Determination of Displacements Using the Multiaxial Convolution Integral

For linear elastic materials, the stress-strain relationship is represented by the generalized

Hooke's law. Assume the rectangular coordinate of x_1 in the horizontal direction, x_2 in

the vertical direction, and x_3 in the depth direction of the IDT specimen. Two strains that

are of interest are ε_{11} and ε_{22}. According to the generalized Hooke's law, these two strains

are related to stresses as follows:

$$e_{11} = \frac{1}{E}(s_{11} - n s_{22}) = D(s_{11} - n s_{22}) \; ; \tag{6.3}$$

$$e_{22} = \frac{1}{E}(s_{22} - n s_{11}) = D(s_{22} - n s_{11}) \, , \tag{6.4}$$

where

      E = Young's modulus and

      D = compliance.

Application of the elastic-viscoelastic correspondence principle to these linear elastic

solutions results in the following linear viscoelastic stress-strain relationships:

$$e_{11} = \int_0^t D(t-t) \frac{\partial}{\partial t}[s_{11} - n(t-t)s_{22}]dt \quad \text{and} \tag{6.5}$$

$$e_{22} = \int_0^t D(t-t) \frac{\partial}{\partial t}[s_{22} - n(t-t)s_{11}]dt . \tag{6.6}$$

The Hondros equations used to calculate the resulting stresses in the horizontal and

vertical directions are:

$$s_{11} = \frac{2P}{pad}[f(x) - g(x)] \quad \text{and} \tag{6.7}$$

$$s_{22} = -\frac{2P}{pad}[f(x) + g(x)], \tag{6.8}$$

where

$$f(x) = \frac{(1 - x^2/R^2)\sin 2a}{1 + (2x^2/R^2)\cos 2a + x^4/R^4} \tag{6.9}$$

$$g(x) = \tan^{-1}\left[\frac{1 - x^2/R^2}{1 + x^2/R^2}\tan a\right]; \tag{6.10}$$

   R = radius of specimen (m);

   x = horizontal distance from center of specimen (m); and

   α = radial angle (radians).

Combining Equations (6.5), (6.6), (6.7), and (6.8) results in the following expressions for

the horizontal and vertical strains:

$$e_{11}(x_1,t) = \frac{2}{pad}\int_0^t D(t-t)\frac{\partial P}{\partial t}\{[f(x) - g(x)] + n(t-t)[f(x) + g(x)]\}dt ; \tag{6.11}$$

$$e_{22}(x_2,t) = -\frac{2}{pad}\int_0^t D(t-t)\frac{\partial P}{\partial t}\{[f(x) + g(x)] + n(t-t)[f(x) - g(x)]\}dt . \tag{6.12}$$

The displacements at the gauge length can be calculated by integrating the non-uniform

strains in Equations (6.11) and (6.12) along the gauge length, i.e., -*l* to + *l*:

$$U = \int_{-l}^{l} e_{11}(x_1, t)dx \; ; \tag{6.13}$$

$$V = \int_{-l}^{l} e_{22}(x_2, t)dx \; ; \tag{6.14}$$

or

$$U = \frac{2}{pad}\int_{0}^{t} D(t-t)\frac{\partial P}{\partial t}\left(\int_{-l}^{l}[f(x)-g(x)]dx + n(t-t)\int_{-l}^{l}[f(x)+g(x)]dx\right)dt \; ; \tag{6.15}$$

$$V = \frac{2}{pad}\int_{0}^{t} D(t-t)\frac{\partial P}{\partial t}\left(-\int_{-l}^{l}[f(x)+g(x)]dx + n(t-t)\int_{-l}^{l}[g(x)-f(x)]dx\right)dt \; . \tag{6.16}$$

For the gauge length of 50.8 mm (2.0 in.), Equations (6.15) and (6.16) reduce to:

$$U = \frac{2}{pad}\int_{0}^{t} D(t-t)\frac{\partial P}{\partial t}\{g_1 + n(t-t)g_2\}dt \; ; \tag{6.17}$$

$$V = \frac{2}{pad}\int_{0}^{t} D(t-t)\frac{\partial P}{\partial t}\{b_1 + n(t-t)b_2\}dt \; , \tag{6.18}$$

where the values of β_1, β_2, γ_1, and γ_2 are shown in Table 2.1.

Equations (6.17) and (6.18) require two time-dependent material properties, i.e., creep compliance and Poisson's ratio. It has been proven that the creep compliance of asphalt concrete can be predicted from the |E*| using theoretical relationships (Kim and Lee, 1995). In this study, the approach is used to convert the |E*| mastercurve to the creep compliance is presented in Section 2.1.

The second time-dependent material property in Equation (6.17) is Poisson's ratio. The time-dependent nature of Poisson's ratio has been reported in Kim *et al.* (2004). Poisson's ratio values for the S12.5C mixture are shown in Figure 6.1 against the reduced time to show a typical trend. These Poisson's ratio values are calculated from Equation (2.12) using the data from the IDT |E*| test. As can be seen in this figure, there is a large

sample-to-sample variability in Poisson's ratio values. Another difficulty involved in Poisson's ratio is that Equation (6.17) is difficult to solve because there are two time-dependent properties in the equation. If Poisson's ratio in Equation (6.17) and (6.18) is assumed to be constant, Equations (6.17) and (6.18) reduce to the following:

$$U = \frac{2(g_1 + ng_2)}{pad} \int_0^t D(t-t) \frac{\partial P}{\partial t} dt \quad \text{and} \tag{6.19}$$

$$V = \frac{2(b_1 + nb_2)}{pad} \int_0^t D(t-t) \frac{\partial P}{\partial t} dt . \tag{6.20}$$
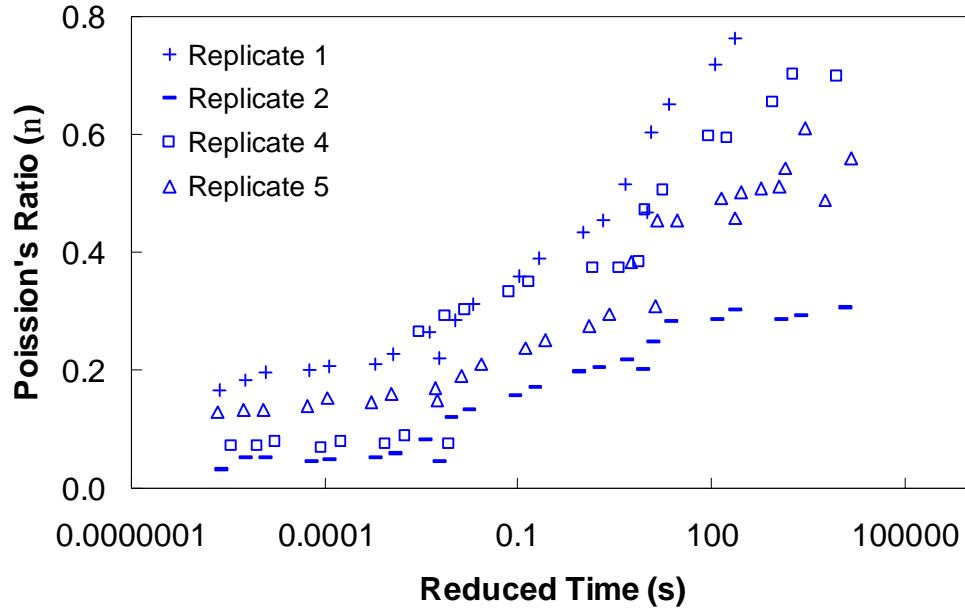

Figure 6.1 Poisson's ratio versus reduced time for S12.5C.

Figure 6.1 presents the measured Poisson ratio's using Equation (2.12). Since the material is viscoelastic, the reduced time is inverse of the reduced frequency multiplied by 0.1. Therefore. small reduced time represents high frequency and low temperature data. The Poisson's ratio is smaller at low temperatures and larger at high temperatures. The measured Poisson's ratio exceeds the theoretical limits of 0.0 to 0.5. A high

Poisson's ratio occurs at large reduced times when the temperature is high and/or the loading time is long. Some Poisson's ratios are higher than 0.5, indicating that damage has occurred in the specimen (Fairhurst et al, 1990, Barksdale *et al.*, 1997). Damage is possible at 35°C, since shear is observable under the loading strips at high stresses. The biggest challenge in determining Poisson's ratio in the IDT test is to induce a large enough horizontal displacement to overcome the electronic noise in the testing system without causing damage in the specimen. Mirza *et al.* (1997) provide a method to evaluate the quality of the data using a deflection ratio.

The effect on M_R, when a constant Poisson's ratio is assumed, is evaluated by using three different Poisson's ratios at each temperature of each mixture and calculating the percentage difference in the predicted M_R values. Poisson's ratio values used in this comparison are 0.15, 0.2, and 0.25 for 5°C, 0.25, 0.3, and 0.35 for 25°C, and 0.4, 0.45, and 0.5 for 40°C. It was found that the difference in M_R values is negligible when Poisson's ratio, which is used to predict the displacements, is used for calculating the M_R. A more in-depth analysis of Equations (2.13) and (6.17) along with the geometry coefficients in these equations, which are shown in Table 2.1 (i.e., k_1, k_2, γ_1, and γ_2), reveals that the effect of change in Poisson's ratio on the term $(k_1 - k_2 n)$ in the numerator of Equation (2.13) is about the same as that on the horizontal displacement calculated from Equation (6.17), which appears in the denominator of Equation (2.13). Therefore, it is concluded that the effect of Poisson's ratio on the M_R calculation is minimal. Vinson drew a similar conclusion that a Poisson's ratio of 0.15 to 0.45 does not affect M_R much, based on theoretical finite-element analysis (1989). For the remainder of this chapter,

Equation (6.19) with constant Poisson's ratios of 0.2, 0.35, and 0.45 for 5°, 25°, and 40°C, respectively, are used.

Because the numerical integration of Equation (6.19) requires calculating all the previous time steps to arrive at the current time step, calculation times can grow exponentially (Underwood *et al.*, 2005). To reduce the calculation time, the state variable approach described in Equations (6.21) to (6.23) is used in this study:

$$e^{n+1} = \int_0^{t^{n+1}} D(t^{n+1} - t) \frac{ds}{dt} dt = h_o^{n+1} - \sum_{i=1}^n h_i^{n+1} , \tag{6.21}$$

where

$$h_o^{n+1} = (D_o + \sum_{i=1}^m D_i)(s^{t^{n+1}} - s^{t^o}) \text{ and} \tag{6.22}$$

$$h_i^{n+1} = e^{-\frac{\Delta t}{t_o}} h_i^n + e^{-\frac{\Delta t}{2t_o}} [s^{t^{n+1}} - s^{t^n}] D_i . \tag{6.23}$$

6.3 Material Information

6.3.1 Measuring Material Properties

The specimens in this study comprise seven different mixtures with four percent air voids listed in Table 3.1. Note the wide range of mixtures necessary to explore the wide range of possible $|E^*|$ values. All the specimens for this study were compacted using a SGC. The $|E^*|$ and M_R were measured from these specimens and used as verification of the ANN.

6.3.2 Database

For this study, the database used to train the ANN was the Witczak $|E^*|$ database. The database consists of over 8000 $|E^*|$ data points from a variety of mixtures. The Witczak

database was selected because it contains 346 mixtures with a large range of values,
especially at high values of the $|E^*|$. For training the ANN, the database was reduced to
210 mixtures because 136 of the mixtures do not have the mixture phase angle data,
which are necessary for the forward modeling process (i.e., predicting the M_R from the
$|E^*|$). The data points for the 210 mixtures were evaluated using internally developed
software. The software fits a sigmoidal mastercurve to the $|E^*|$ data for each mixture, then
calculates creep compliance. The creep compliance is necessary for Equation (6.2). A
few more mixtures were removed due to curve fitting issues, reducing the database to 206
$|E^*|$ and M_R pairs. After obtaining the creep compliance, the response to a M_R loading
history was simulated (*e.g.*, using a 10 Hz haversine pulse with a 0.9 second rest period)
at three temperatures. From this simulated response history, the M_R was determined.
Then, the resilient moduli were calculated for each mixture. Of the 206 available
mixtures, ten were randomly removed from the training database. After training the
ANN, these ten mixtures were used to evaluate the predictive capabilities of the trained
ANN of data with similar variability as the training set. After verifying the predictive
capabilities, the predictive accuracy of the ANN was verified by using measured data
acquired for the mixtures previously listed.

6.4 Developing Forward Model
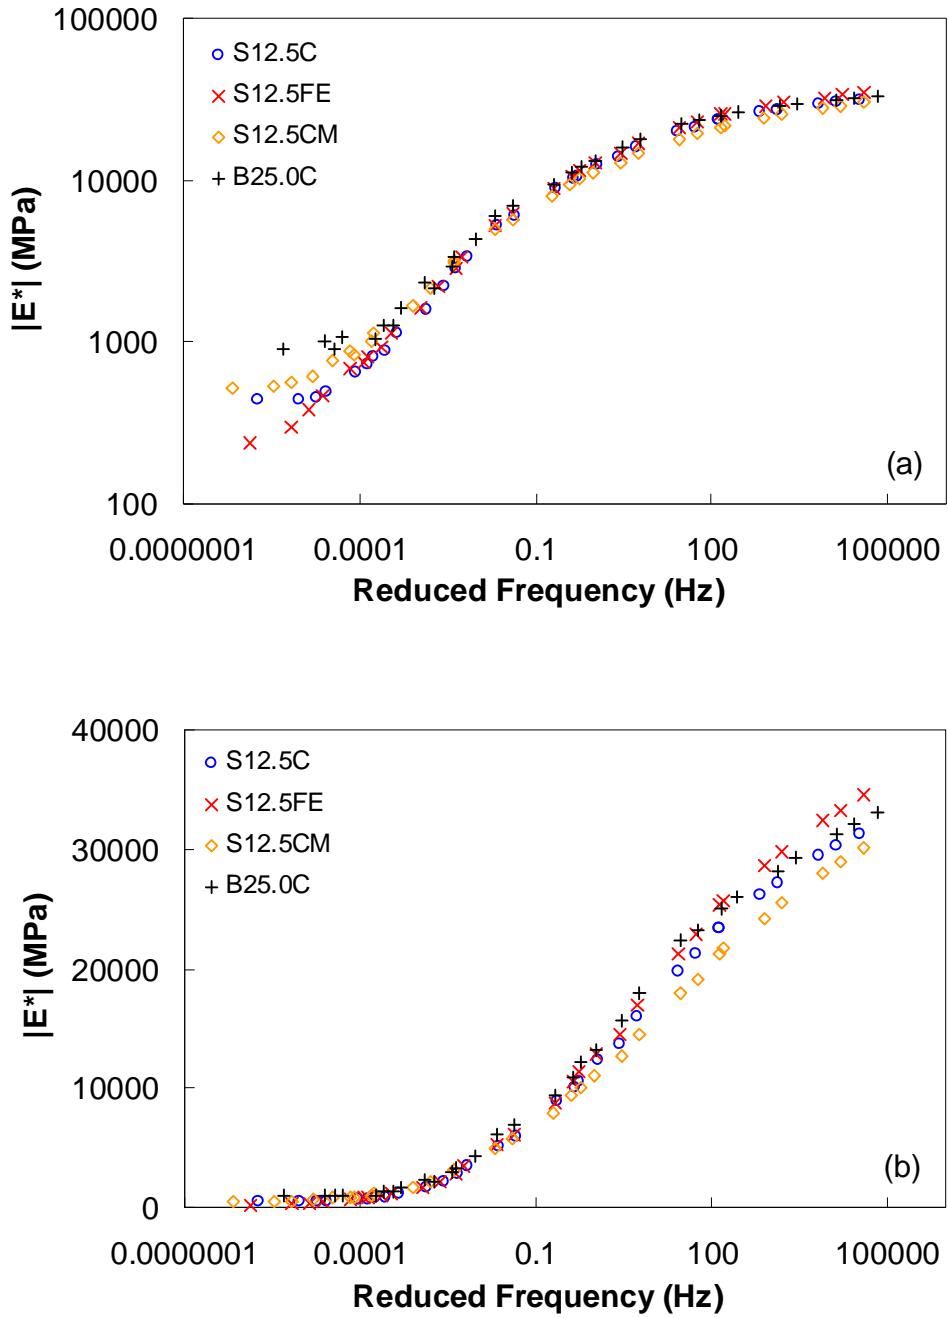

Figure 6.2 Average |E*| mastercurves: (a) in log-log scale and (b) in semi-log scale.

The |E*| mastercurves for the four mixtures are plotted in Figure 6.2. It can be seen in Figure 6.2(b) that |E*| of the S12.5FE mixture is slightly higher than B25.0C which is slightly higher than the S12.5C mixture at high reduced frequencies. At low reduced frequencies, these S12.5C and S12.5FE mixtures exhibit essentially the same stiffness characteristic as shown in Figure 6.2(a). The variation of the stiffness at high reduced frequencies (i.e., low temperatures) appears to be the result of sample-to-sample variability in the averaging of each mixture. The same dynamic moduli at small reduced frequencies (i.e., high temperatures) indicate that the effect of flat and elongated aggregate particles in the S12.5FE mixture on the |E*| is minimal. This observation suggests that the |E*| testing with small strain amplitudes cannot capture the effect of the aggregate structure.

The slightly higher |E*| of B25.0C at small reduced frequencies than those of the 12.5 mm mixtures may be due to the pronounced effect of larger aggregates at high temperatures. Comparison of the |E*| mastercurves from S12.5C and S12.5CM reveals the effects of binder modification on |E*| values. At high reduced frequencies (i.e., low temperatures), the SBS modified mixture is less stiff. At low reduced frequencies (i.e., high temperatures), the binder modification makes the mixture stiffer, which demonstrates the benefit of the SBS modification of the binder.

The horizontal strain is predicted from Equation (6.11) using the measured IDT |E*| shown in Figure 6.2 and a constant Poisson's ratio for each temperature. Time histories of the predicted and measured horizontal strains are plotted in Figure 6.3 through Figure 6.5. In these figures, vertical strains have a minus sign because they are in compression

whereas the horizontal tensile strains have a plus sign. There are two parameters to compare in Figure 6.3; one is the mean strain, and the other is the strain amplitude. It can be seen in Figure 6.3 that the prediction is quite good at 5°C for both the mean strain and strain amplitude for both vertical and horizontal strains. However, at 25° and 40°C in Figure 6.4 and Figure 6.5, the prediction of the strain amplitudes is reasonable as seen by comparing the shifted measured strain versus the predicted strain. The shifted strain was calculated by subtracting the difference between the measured and predicted strains at relative time of zero from the measured strain.

As can be seen in Figure 6.4 and Figure 6.5, the mean strain prediction is poor. At 25° and 40°C, the measured mean strains are much greater than the predicted mean strains for both vertical and horizontal strains. This difference indicates that the IDT |E*| testing causes a significant permanent deformation, which cannot be predicted from the proposed approach in this paper using the theory of linear viscoelasticity. The fact that the strain amplitude prediction is reasonable even with a significant permanent deformation supports the earlier observation made from the same |E*| between the S12.5C, S12.5FE, and B25.0C mixtures; that is, the small stresses and strains used in the |E*| testing do not capture the effect of changes in the aggregate structure.
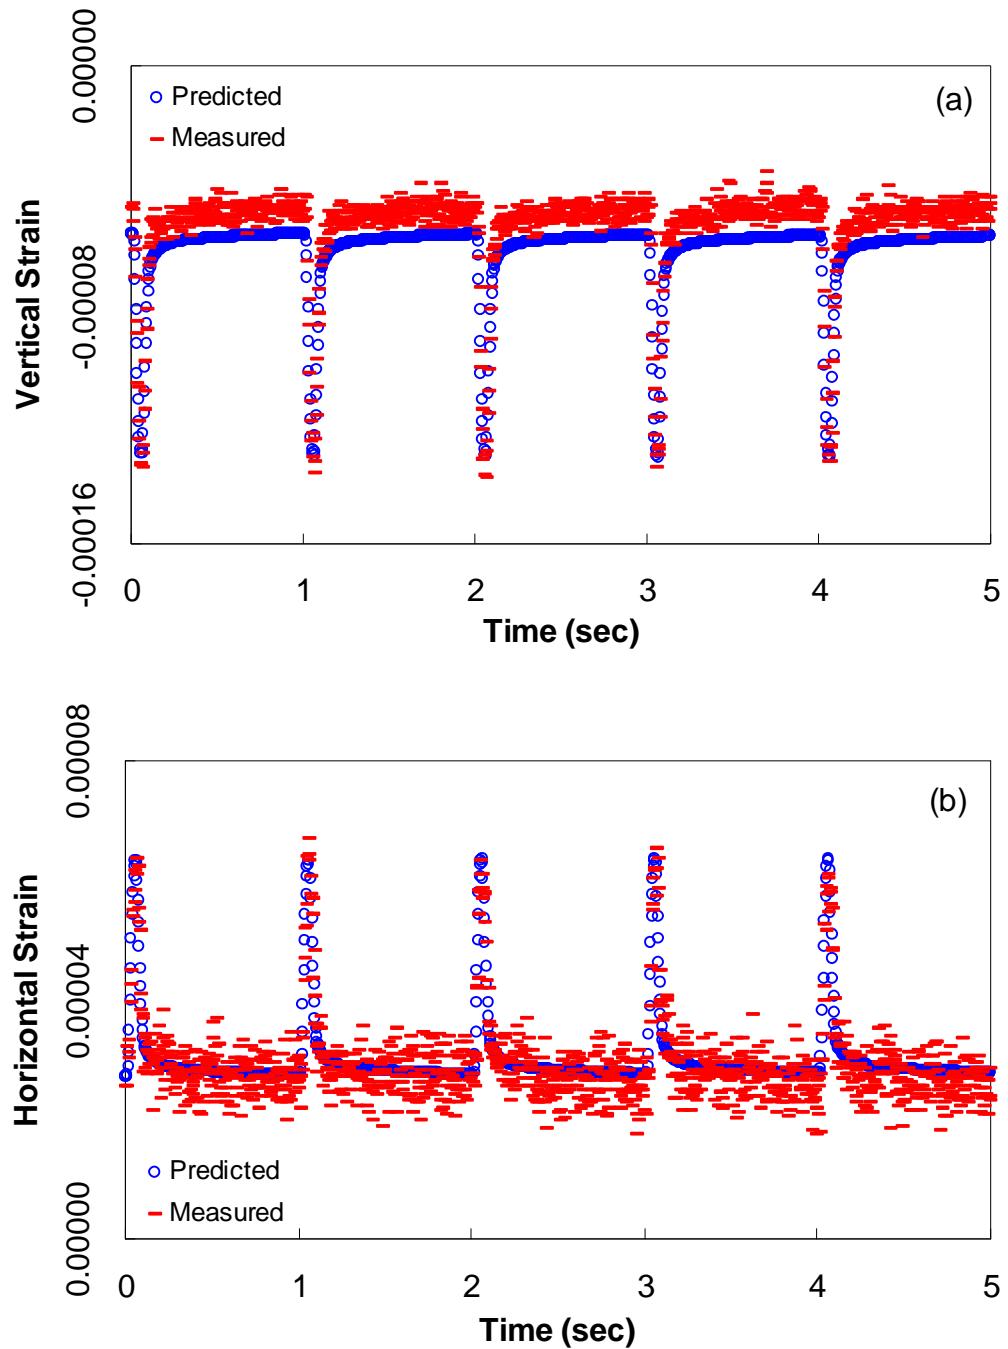

Figure 6.3 Strain comparison for $\nu = 0.20$ at 5°C: (a) vertical and (b) horizontal.
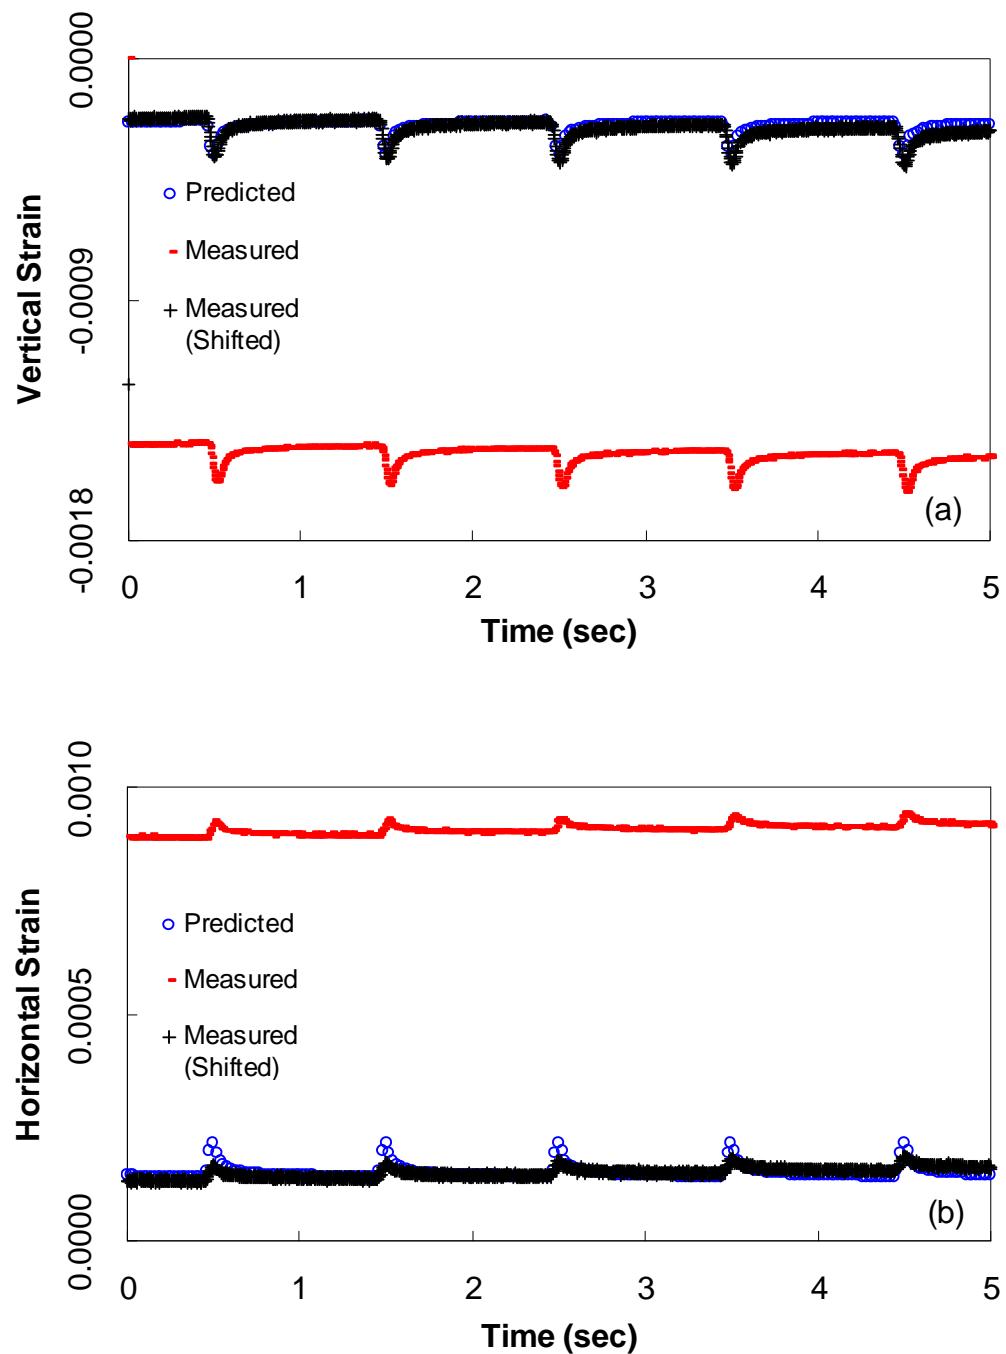

Figure 6.4 Strain comparison for $\nu = 0.35$ at 25°C: (a) vertical and (b) horizontal.
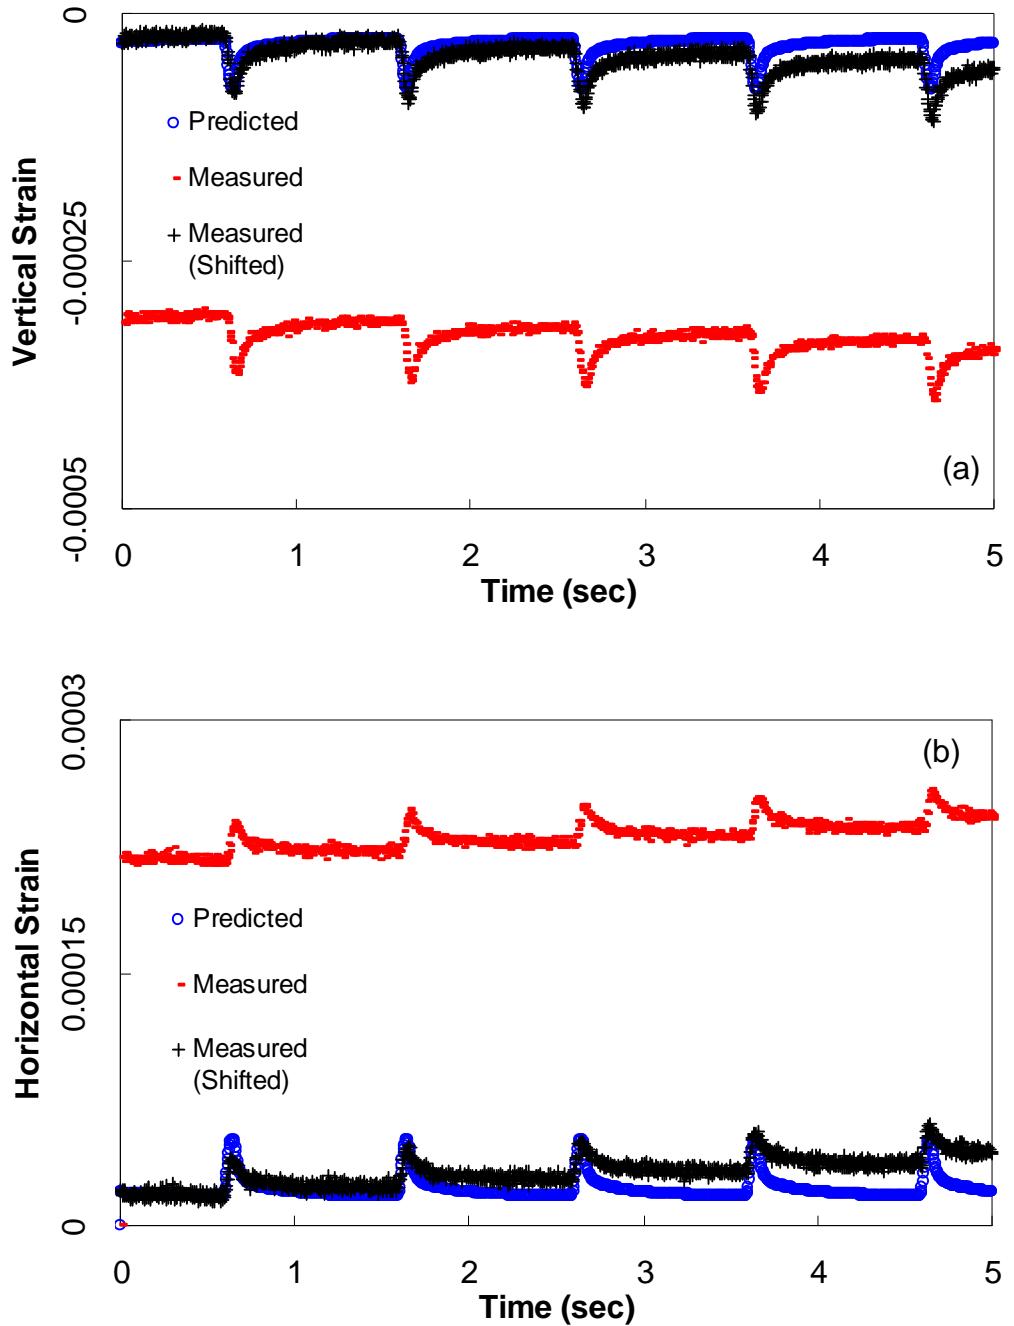

Figure 6.5 Strain comparison for $\nu = 0.45$ at 40°C: (a) vertical and (b) horizontal.

Table 6.1 Comparison of Predicted and Measured M_R Values

S12.5C				
	Measured M_R (MPa)		Predicted M_R (MPa)	
Temperature (°C)	Mean	Standard Deviation	Mean	Standard Deviation
5	20,300	1,800	20,100	280
25	5,460	320	5,980	100
40	2,100	410	1,880	100
S12.5CM				
	Measured M_R (MPa)		Predicted M_R (MPa)	
Temperature (°C)	Mean	Standard Deviation	Mean	Standard Deviation
5	18,360	1,560	17,700	370
25	5,990	940	5,470	60
40	1,540	160	1,640	50
B25.0C				
	Measured M_R (MPa)		Predicted M_R (MPa)	
Temperature (°C)	Mean	Standard Deviation	Mean	Standard Deviation
5	21,200	1,340	21,600	20
25	6,200	270	6,560	110
40	1,640	80	2,270	60
S12.5FE				
	Measured M_R (MPa)		Predicted M_R (MPa)	
Temperature (°C)	Mean	Standard Deviation	Mean	Standard Deviation
5	20,700	2,540	20,600	410
25	5,800	1,050	5,810	260
40	1,740	350	1,630	60

Since the ultimate objective of task one is to evaluate the prediction accuracy of the proposed approach to M_R determination, Equation (6.19) is used to predict the M_R for each specimen. In this prediction, the load history specific to each specimen is used. Also, Poisson's ratio values of 0.2, 0.35, and 0.45 are used for 5°, 25°, and 40°C analysis, respectively. Table 6.1 presents the mean and standard deviation of the measured and predicted M_R values for all the conditions tested in this study. All the predictions except

40°C data from B25.0C are within two standard deviation of the measured average value, which means the predicted value has a 95% probability of falling within a normal distribution of the measured data.
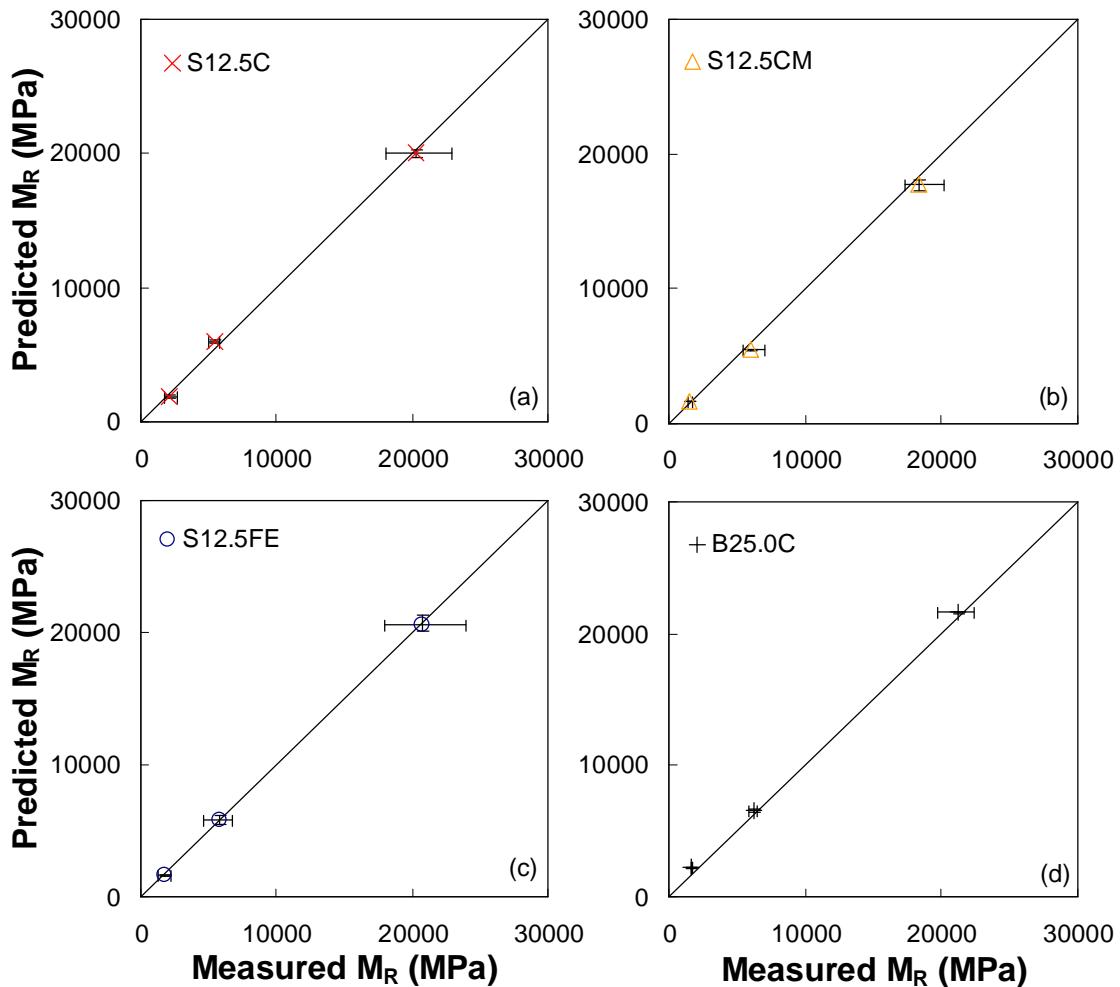

Figure 6.6 Comparison of predicted and measured M_R values: (a) S12.5C, (b) S12.5CM, (c) S12.5FE, and (d) B25.0C.

6.5 Training the ANN

The second step in predicting the M_R from the $|E^*|$ is training the neural network. The ANN was trained using the neural network toolbox in MatLAB®. Once the ANN is trained, the output file containing the ANN structure can be implemented in any

commonly available computer language. The inputs to the ANN were three M_R values at

three different temperatures along with the reduced frequencies of 10 Hz at those three

temperatures. The reduced frequencies are calculated at the reference temperature of

10°C. Since the frequency of an M_R pulse is difficult to determine (Loulizi, 2006), the

frequency was selected to correspond with the loading pulse. Even if the M_R is equal to

the |E*| at a frequency other than 10 Hz, the ANN will compensate for that in its transfer

functions. As long as the inputs are calculated the same way, the results are not affected

by the choice of 10 Hz. The ANN was trained to predict the four coefficients describing

the sigmoidal function in Equation (2.8) that represents the dynamic modulus

mastercurve.

   The time-temperature superposition principle states that unit response functions (e.g.,

dynamic modulus) in thermorheologically simple materials, such as HMA, can be shifted

in the time or frequency domain (i.e., the horizontal axis) to produce a single, continuous

mastercurve as shown in Section 2.1. Since the loading frequency used in the M_R testing

is a single frequency of 10 Hz, prediction of the |E*| at multiple frequencies requires

additional information. The best candidate to handle this frequency issue is the mixture

time-temperature shift factor in Equation (2.7). However, determination of the mixture

shift factor requires the dynamic modulus data at multiple temperatures and frequencies,

which is the information to be predicted from the ANN model.

   In order to break this circle, it is proposed to use binder shift factors in place of mixture

shift factors. Dongre *et al.* (2005) provided evidence that the mastercurves generated

from binder and mixture shift factors are the virtually the same. Further evidence of this

correlation is shown in Figure 6.7. The binders shown in the study are binders used in a current FHWA pooled-fund study. The binder types are modified binders labeled as PG70-22, CRTB (Crumb Rubber Terminal Blend), SBS, and Elvaloy. The binder testing was done by FHWA for the project. The mixture testing was done at North Carolina State University. Figure 6.7 shows the shift factors from measurements at 5°, 25°, 40°, and 54°C for both mixtures and binders. Binder DSR testing was performed at 7°C, so minor extrapolation was applied to determine the shift factors at 5°C. As seen from the figure, the values are very close to the line of equality. In many cases, the values are almost numerically exact. Based on the observations of Dongre *et al.* and these results, it is reasonable to use binder shift factors to determine the mixture $|E^*|$ values at multiple frequencies from the single frequency M_R data.
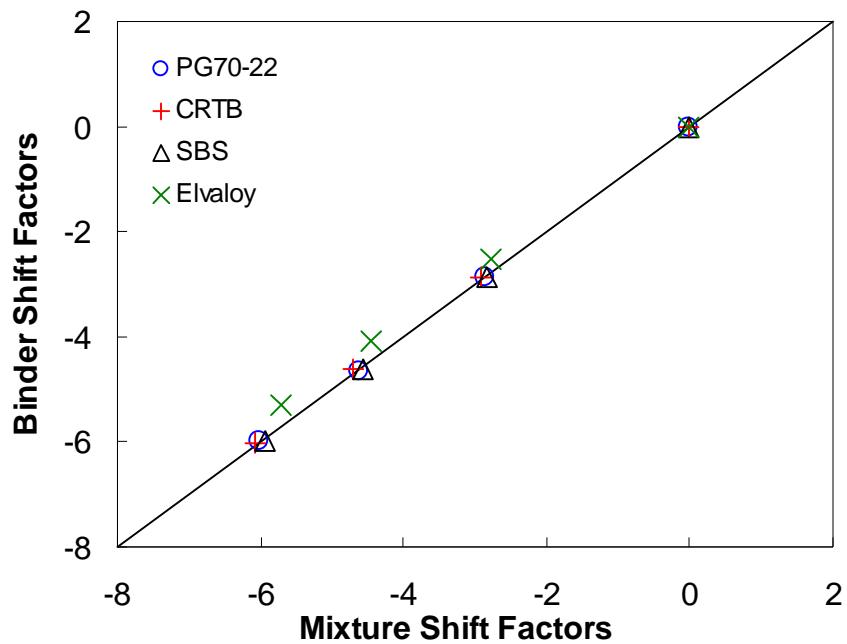

Figure 6.7 Line-of-equality graph for mixture and binder shift factors from FHWA study.

6.6 Verification of the ANN

The first step of verification is evaluating the predictive capabilities of the ANN using the
data employed in the ANN training. As seen in Figure 6.8, the ANN results are around
the line-of-equality. The prediction accuracy of the modified Witczak's model, which
includes binder |G*| or shear modulus as an input (Bari and Witczak, 2007), is also
shown in Figure 6.8. The comparisons in the figure are circular since the data used in
evaluating the prediction accuracy were used in defining the models. The ANN shows
less bias than the Witczak prediction. The Witczak prediction tends to over predict the
modulus at high modulus values. The figure also shows how the nonlinear transfer
functions can reduce the error for a training dataset when compared to the regression
analysis used in the modified Witczak's model..
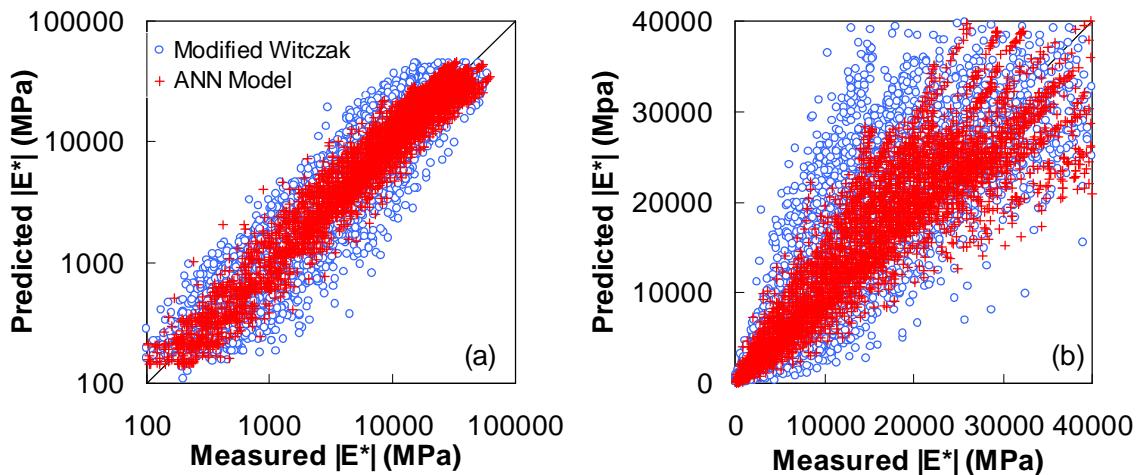

Figure 6.8 Line-of-equality graph of training data: (a) log-log and (b) arithmetic scales.

After the first verification, the ANN was further verified using two additional
comparisons. The first comparison used a dataset of predicted M_R values and measured
|E*| values composed of ten mixtures reserved from the Witczak's database. This dataset

was used to test the soundness of the ANN, assuming that the variability was similar to the variability of the training dataset. Also, this dataset provides the same framework as the ANN training dataset because the M_R values are predicted and not measured. The second dataset consists of measured M_R and |E*| values from the seven North Carolina mixtures. This dataset should yield the ultimate verification of the ANN model as well as show any differences between the Witczak and independent |E*| values, because the trained ANN is based on the Witczak data.

As seen in Figure 6.9, the ANN prediction for the first dataset is good considering the spread of data seen in Figure 6.8. In log-log scale, the variability is generally constant. In arithmetic scale, the variation is greater at large modulus values. It is noted that the comparison for the modified Witczak model is circular; i.e., the data shown in Figure 6.9 were used in developing the modified Witczak model. The ANN prediction is not circular because these data were not included in the ANN training set. The more accurate prediction of the ANN model compared to that of the modified Witczak model may be attributed to the superior ability of the ANN to describe the complex relationship between the M_R and |E*| values and/or the fact that the ANN model predicts the mixture property |E*| from another mixture property M_R, whereas the modified Witczak model predicts the mixture |E*| from component material properties.
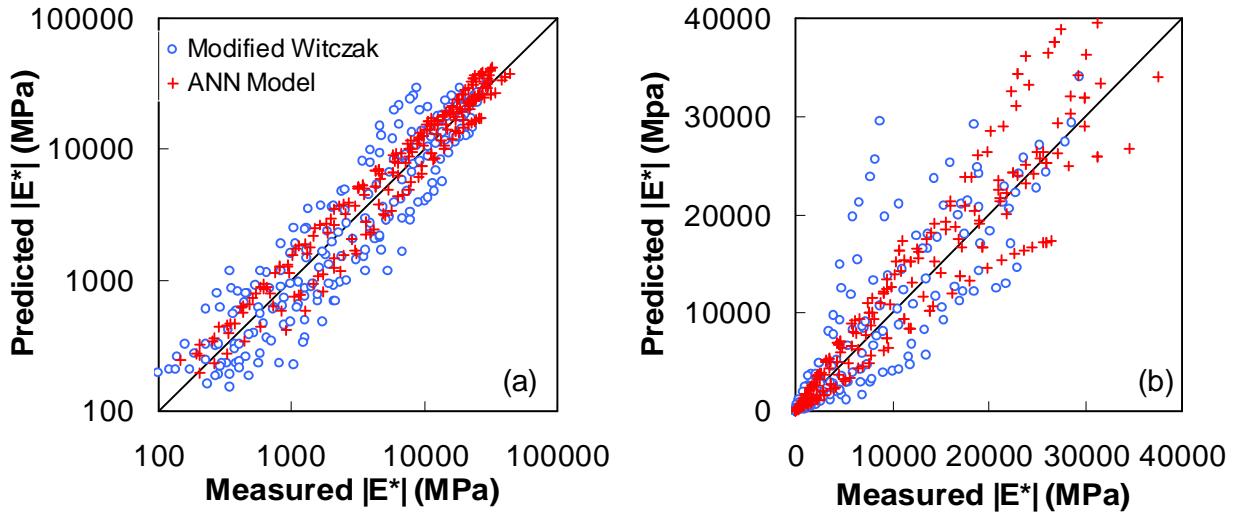

Figure 6.9. Line-of-equality graph of verification using Witczak data (a) log-log and (b) arithmetic scales.

The second verification of the ANN is performed using an independent source of data.

Figure 6.10 shows the results of the prediction for the independent North Carolina

database. Two observations can be made from this figure. First, predictions from both the

ANN and the modified Witczak model show less variability than the training data shown

in Figure 6.9. Because all the tests for the North Carolina database were performed by a

single operator during a relatively short period (within a year), the independent database

is expected to include more consistent quality data than the Witczak database that was

developed by multiple operators over a much longer period. This additional consistency

in the North Carolina database may be the reason for less variability seen in Figure 6.10

than that seen in Figure 6.9. The second observation is the slight underestimation of the

|E*| values by the ANN model. It is assumed that this bias is the result of using two

different databases. In training the ANN, the targeted |E*| values came from the Witczak

database. The independent verification of the ANN used |E*| values measured for this

study. The difference between the measurements of the Witczak |E*| and the |E*| of this

study is the difference in strain levels employed in the |E*| testing. The strain levels
reported in the Witczak database are quite often greater than 100 microstrains (Bari
2005), whereas the North Carolina testing kept the strains below 75 microstrains. The
lower strain level has a lower probability of damaging the specimen, and therefore a
greater probability of larger |E*| values. This observation is supported by the fact that the
modified Witczak model displays a similar underestimation of the |E*| values. Again, the
different strain levels used in the Witczak and North Carolina databases explain this
trend. One way to reduce this bias is to retrain the ANN model using the data from both
the Witczak and North Carolina databases.
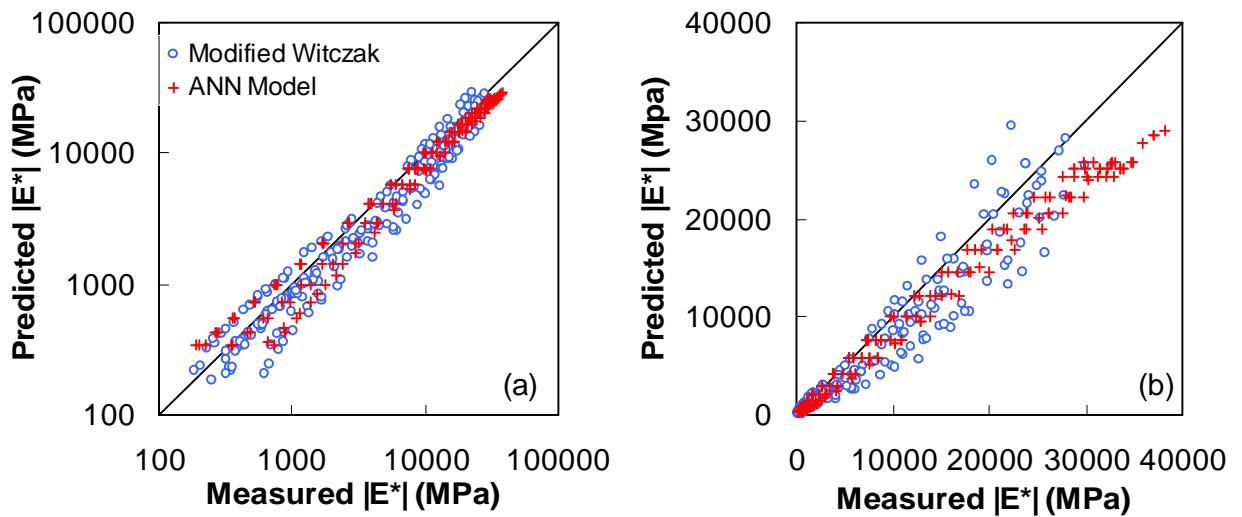

Figure 6.10. Line-of-equality graph of verification data (a) log-log and (b) arithmetic scales.

To determine if the level of accuracy, in the ANN model is adequate, as shown in Figure
6.10, the effect of the changes in the modulus on performance results has been evaluated
using the MEPDG. The performance predictions based on the measured and predicted
|E*| data calculated by the MEPDG are presented in Table 6.2. The measured |E*| values
were obtained from the S12.5C mixture. The M_R values for the mixture were used to

predict the |E*| values. To characterize the predicted |E*| values, a linear regression was

generated through the ANN data in Figure 6.10. The error was approximately 15%,

similar to the error observed by measuring the |E*| with different geometries. Therefore,

this comparison also allows the evaluation of the quality of data from different

geometries as well as the predictions of the ANN. The measured and predicted |E*|

values were used to predict the performance of both a thin and a thick pavement with

different loading levels.

Table 6.2. MEPDG Performance Predictions Based on Measured and Predicted Data

Performance Criteria	Distress Target	Source of |E*|		ANN/Measured Ratio
		ANN	Measured	
10" Asphalt, 6" Aggregate Base AADTT = 8000				
Terminal IRI (in/mi)	172	120.9	118.4	1.02
AC Bottom Up Cracking (%):	25	7.6	5.6	1.36
Permanent Deformation (AC Only) (in):	0.25	0.13	0.12	1.08
4" Asphalt, 8" Aggregate Base AADTT = 300				
Terminal IRI (in/mi)	172	122.7	119.5	1.03
AC Bottom Up Cracking (%):	25	2.5	1.8	1.39
Permanent Deformation (AC Only) (in):	0.25	0.32	0.27	1.19

Note that the |E*| is a small strain measurement and provides a pavement response at

similar levels. Performance evaluations concerning permanent deformation and cracking

occur at high strain levels. Therefore, differences in the |E*| values – without including

the changes in performance prediction model coefficients – may not provide an accurate

evaluation. With this limitation in mind, the following comparisons are made. For both

cases, the predicted |E*| values do not change the conclusions of the analysis. For

example, the bottom up cracking ratio is large, but the values in both pavements are small

compared to the failure criteria. In the thin pavement example, the pavement fails the

permanent deformation criteria in both cases. The results imply that the IRI model is not

strongly influenced by the |E*| input. The predicted |E*| values provide similar performance results with consistent conclusions compared with those of the measured |E*| values.

6.7 Conclusions

The results show that using the M_R to predict the |E*| is possible using an ANN. Also, given the appropriate models, significant work and time can be saved by predicting a value instead of measuring it. A |E*| prediction methodology is developed using the ANN. This methodology uses the M_R values and binder time-temperature shift factors as inputs. The following three steps were conducted for verification: (1) prediction of the |E*| data in the Witczak database, which are used in the ANN training; (2) prediction of the |E*| data in the Witczak database, which are not used in the ANN training; and (3) prediction of the |E*| data from an independent database composed of seven North Carolina mixtures. In all three verification steps, the ANN model shows a better prediction accuracy than the modified Witczak model. A slight bias is observed in the third verification study that employs the independent North Carolina database. This bias, observed in both the ANN and modified Witczak models, may be due to the different strain levels used in the Witczak and North Carolina databases. Effects of this bias on the pavement performance are evaluated from limited MEPDG analyses and found to be insignificant. The developed ANN model is a reasonable method of populating the LTPP Materials database with |E*| values using M_R values, provided binder shift factor information is known.

As mentioned earlier, the ANN was created using a MatLAB® toolbox. Any standard programming language can use the output of the training session to recreate the neural network. For the pavement engineers, this provides an accessible product in which they provide the inputs, *i.e*. M_R values and reduced frequencies, and the program provides the sigmoidal shift factors. In this case, databases, such as the LTPP materials database, can be updated with |E*| at least as accurately as using other models.

CHAPTER 7   SUMMARY AND FUTURE RESEARCH

As mentioned in the Introduction, when applying mechanistic and mechanistic-empirical methods to pavment design and rehabilition, knowing the material property is important. As shown, the predictions in MEPDG are not significantly sensitive for a thin and thick pavement to variations in dynamic modulus as large as 15%. The preferred method for acquiring |E*|is measuring the material response using the standard axial specimen. The dynamic modulus should be measured for most projects when the road is built to have a database of the initial stiffness of the pavement. When this in not possible, i.e. an in-place pavement, another method such as IDT testing is an alternative. The second option allows for better rehabilitation design since one would know the |E*| at a few points along the road. The challenge would be acquiring the data fast enough, since testing takes time. For this reason, most moduli values are determined using falling-weight deflectometer (FWD). A third alternative is is to predict the |E*| from the M_R. This alternative is the most desireable for populating the LTPP materials database since binder information is more readily available.

The latter two options provide viable methods for populating the LTPP materials database. To balance accuracy with expediency, both require some testing to adequately characterize the mixtures for predicting pavement performance with the MEPDG. With the additional pavement performance predictions, an estimate of the accuracy of MEPDG performance predictions can be made by comparing predictions to field observations collected for LTPP pavement sections.
