Abstract

Knowing the long-term performance of geothermal energy extraction is crucial to decision-makers and reservoir engineers for optimal management and sustainable utilisation. This article presents a three-dimensional, numerical model of coupled thermo-hydraulic processes, in a deep heterogeneous geothermal reservoir overlain and underlain by impermeable layers, with discrete fracture. The finite element method is employed in modelling the reservoir, after conducting a verification study to test the capability of the solver and the results obtained are in agreement with the existing models. The model is then used to investigate the responses of human control parameters (injection flow rate, fluid injection temperature, and lateral well spacing) on reservoir productivity, using different operation scenarios. The injection flow rate is found to be more efficient, concerning reservoir productivity, than the other two parameters. To this end, the study concludes that, by varying some parameters in the subsurface, reservoir productivity can be optimised efficiently. The numerical model developed provides in-depth insight to stakeholders and reservoir engineers concerning the essential parameters to control during exploration and exploitation.

1. Introduction

Geothermal energy is a base load energy resource that is available universally beneath us in great quantity. One form of this resource is the deep geothermal system, from which energy is mined by forcing circulating fluids via an injection well to create a reservoir and then extracting the fluid back through a production well in a closed loop [1]–[4]. Before exploiting the energy, preliminary studies on the geological formations and petrophysical properties of a selected field needed to be conducted. However, field experiments are very expensive to perform [5], and the long-term performance of the systems should be investigated before engagement. Numerical modelling can provide essential information that will guide in determining the long-term performance of geothermal systems. To simulate and evaluate the behaviour of a deep geothermal system for its commercial viability, a reliable numerical method that can handle the complexity of subsurface flow is needed [6]. The modelling of geothermal systems has become a useful technology with applications to more than 100 fields worldwide [7]. Also, computational meshes of large, complex, three-dimensional models with more than 4000 blocks are now used routinely [7]. The first development of a geothermal reservoir simulation took place in the early 1970s [8]. However, the most accepted one in the geothermal industry was the 1980 code comparison exercise organised by the US Department of Energy [9], which consisted of testing several geothermal simulators on a set of six test problems. As a result, a progressive improvement in the capabilities of simulation codes for geothermal reservoir modelling has been acquired.

There have been substantial advances in numerical simulation for geothermal reservoirs over the past several decades, with the steady growth of computational power and the development of numerical models that have minimised several simplifying hypotheses. The advances include the implementation of more accurate equations of state for the fluid system, for instance, in the TOUGH2 and TOUGHREACT codes and the FALCON code [10]–[12]. Also, there has been tremendous progress in the ability to represent geometric complexity and heterogeneity in simulation codes; examples include FEFLOW, GOCAD, and OpenGeoSys [13], [14]. Computational schemes that are faster and more accurate have also been elaborated in reservoir simulation. Other numerical simulation codes are still under development, especially those by the current reservoir modelling working group, inaugurated with the help of the International Partnership for Geothermal Technology (IPGT). The IPGT is an international organisation with five member countries (Australia, Iceland, New Zealand, Switzerland, and the United States) aiming to improve understanding of geothermal potentials and usage in the globe [15]. The organisation proposed to develop a standard

80   geothermal simulation code that will couple the various interactions arising during

81   exploitation by the year 2020. The Geothermal Technology Office (GTO) under the Energy

82   Department of the United States has initiated a code comparison study program that will

83   improve the state of the art of geothermal simulation codes [16]. The program focused on

84   examining existing codes, identifying dissimilarities, and illustrating the modelling

85   capabilities of a global compilation of several numerical simulators for assessing geothermal

86   technologies. Six benchmark problems were proposed, and the program commenced in 2014.

87   According to White and Phillips [17], 12 groups participated in the challenge, and each group

88   had a unique numerical simulator and analytical approaches providing a detailed mechanistic

89   approach, modelling process, and solution scheme. Ghassemi et al. [18] reported on some of

90   the outcomes of the program, stating that none of the 12 members was able to participate in

91   all six problems due specifically to code limitations.

92   Therefore, geothermal modelling tools exist for several decades, but they were unable

93   to cope with modern demands, both in resolving scientific and resource specific questions

94   and in computational practicability [19]. Although concepts can be rigorously tested for

95   consistency with data as soon as these become available, it is never early to establish a

96   computational model [18]. An appropriate numerical modelling tool is vital in planning the

97   energy extraction operations. The essential key instruments in planning the operations include

98   parametric studies. Shook [21] conducted an extensive study on some naturally occurring

99   parameters and their effect on energy recovery using the TETRAD code by employing the

100   geysers' geothermal data. The parameters include capillary pressure and relative permeability

101   relationship, initial liquid saturations, fracture spacing, and geologic structure. Nalla et al.

102   [22] studied the effect of formation properties and operational variables of wellbore heat

103   exchangers (WBHX) for enhanced geothermal systems (EGS) using the TETRAD simulation

104   code. Vacchiarrelli et al. [23] carried out a parametric study on the effects of fracture aperture

105   and fracture rotation angle on reservoir productivity by applying the GEOCRACK simulation

106   code. Recently, Chen and Jiang [24] reported the heat extraction performance of EGS using

107   different wellbore layout configurations. The layout investigated include doublet, triplet-

108   straight line, triplet-triangle, and quintuplet. Jain et al. [25] examined the effect of various

109   wellbore arrangements under different injection rates by employing the SHEEMAT

110   simulation code. The injected rates employed were 50 l/s, 100 l/s and 150 l/s, and the

111   wellbore configurations studied include doublet, triplet, and reversed-triplet. Poulsen et al.

112   [26] analysed the effect of thermal conductivity of confining beds, production rate, injection

113   temperature, and reservoir thickness on the productivity of low enthalpy geothermal

4

114 reservoirs. Aliyu et al. [27] studied the effect of extraction well placement on geothermal

115 productivity using the dual porosity approach.

116   Especially, not much attention has been paid to the parametric studies on human-

117 controlled parameters in geothermal energy extraction. Bedre and Anderson [28] first

118 introduced the idea by analysing naturally occurring parameters and human-controlled

119 parameters of low-enthalpy geothermal systems in the United States using the 'One Factor At

120 a Time' (OFAT) method. Saeid et al. [29] developed a prototype model capable of estimating

121 the lifetime of low-enthalpy systems, based on the OFAT method proposed in [28]. In [28]

122 the reservoir is represented as a three-dimensional (3-D) model with the assumption of a

123 simplistic porous media approach for the fracture systems using the TOUGH2 five-spot

124 model, whereas in [29], the contributions of fracture systems is ignored in their representation

125 but an explicit 3D model of the reservoir is depicted with underlying and overburdened strata.

126 It can be summarised from the above literature that the previous research focuses specifically

127 on low-enthalpy geothermal systems, naturally occurring parameters, and stochastic

128 modelling tools in the reservoir representations. Thus, not much has been reported on human-

129 controlled parameters in geothermal energy extraction, more specifically on enhanced

130 geothermal systems with open boundaries.

131   In this study, a 3-D numerical model of a deep and heterogeneous geothermal

132 reservoir is developed with a discrete fracture using the Soultz EGS scheme. The system

133 proposed here considers the influence of the surrounding media, the reservoir, and the

134 fractures concurrently in the estimation of the effect of human control parameters on

135 geothermal energy extraction. In this model, the fluid is circulated through an inclined

136 vertical well connected to the matrix (i.e., not a fracture) in a fully saturated porous medium,

137 unlike the previously reported models in which the injection and the production wells

138 communicate via a single planar fracture or multiple. Although, a fracture is also included in

139 this model that intersects the matrix at an angle but without connecting the wellbores to

140 communicate. The reason for these assumptions in the current model is that sometimes the

141 wellbores do not connect through fractures, as in the case of Soultz triplet geothermal

142 reservoir where a low connection between GPK3 (injection well) and GPK4 (the second

143 production well) is experienced due to calcite deposition [30]. Moreover, the geothermal

144 reservoir is modelled as an open system that allows for additional sources or losses from the

145 surrounding boundaries. As a result, water losses in the reservoir are accounted for in the

146 model. The significance of this assumption can be supported by a real-life case of an existing

147 geothermal reservoir. For instance, the five-month circulation test regarding hydraulics,

148   conducted in the Soultz geothermal reservoir during 2005, showed that only 30% of fluid

149   mass injected is recovered at the production wells, displaying the open nature of the reservoir

150   [31]. The test result opposed the hot dry rock (HDR) concept that considered the reservoir to

151   be a closed system with no naturally existing fluid present before its injection [32].

152   The contribution of the present work includes these three aspects. First, this study has

153   proposed a mixed transport of fluid and heat in the reservoir from both the matrix block and

154   the fracture, respectively. Second, the 3-D model takes into account the effect of fluid losses

155   or gains concerning the nature of open systems in subsurface media, whose long-term

156   influence on the extraction wellbore temperature cannot be underestimated for a 30-year

157   extraction period. Third, in this investigation, each of the human-controlled parameters

158   (injection flow rate, injection temperature, and lateral well spacing) are examined under

159   different operational scenarios with other parameters. For example, injection flow rate in this

160   study ranges from 20 l/s to 70 l/s. Therefore, when examining the effect of the injection flow

161   rate on production, different cases of injection temperature and well spacing are considered,

162   because their impact can also affect reservoir productivity.

163   The model addresses the limitations of previous research, which ignored the influence

164   of fractures, reservoir representation, open boundaries influence, and the inclusion of

165   different operational schemes. The study estimates the consequence of individual parameters

166   on others and their corresponding influences on the productivity of a geothermal reservoir.

167   Solving the structure of this heterogeneous system, which is nonlinear in parameters and has

168   a coupled interaction in nature, requires the use of a powerful numerical solver. The finite

169   element method (FEM) is adopted here because of its robustness in dealing with such

170   problems. The FEM package employed in the study is COMSOL with a link to MATLAB

171   that serves as a framework for implementing the numerical model and making the required

172   coupling between the physics [33]. At the end, numerical studies are carried out to verify the

173   developed model, and sensitivity analyses are performed to investigate the influence of the

174   parameters on reservoir productivity.

175

2. Modelling thermo-hydraulic coupled problems

177 The first step in the analysis of coupled fluid flow and heat transport problems consists of

178 defining the geometry, material properties, initial and boundary conditions [34]. The

179 geometry can be created or imported from a CAD program once it is developed by including

180 the material properties and initial and boundary conditions. The next step is defining the

181 mathematical model and coupled processes to be solved. The final two stages are independent

182   of the type of numerical technique employed in solving the mathematical model except that

183   the chosen solution procedures should be capable of solving the model accurately.

184   Modelling geothermal energy exploration and exploitation requires coupling the

185   complex interaction occurring among different phenomena in the subsurface. These

186   phenomena include fluid flow, heat transport, chemical transport and mechanical

187   deformation. However, this study is limited to the coupled processes of heat transport and

188   fluid flow in a fully saturated and fractured porous media. Figure 1 presents the two-way

189   coupled approach used in this study, the illustration showed the hydraulic process is affected

190   by temperature gradient directly through the change in density and viscosity of the fluid, and

191   the thermal process, on the other hand, is influenced by the convective heat transfer through

192   Darcy's velocity term. For further details on coupled processes in the field of geosciences see

193   [35].

194

195   The macroscopic governing equations describing the behaviour of the fully coupled TH

196   model demonstrated in the previous section compels the application of conservation laws of

197   energy and mass. In this study, the derived equations are based on a dual porosity-

198   permeability model (the model that accounts for rock matrix and fracture properties as a

199   separate continuum). Therefore, this section will derive the partial differential equations for

200   both the fluid flow and heat transport using the dual porosity-permeability approach are given

201   here.

202   The law of conservation of mass governs the fluid flow expression in porous media,

203   and the law states that the mass inflow subtracted by the mass outflow is equal to the total

204   mass accumulated by a system. Thus, the conservation of mass fluid in porous matrix system

205   is

206
$$\frac{\partial}{\partial t}(\rho_L \phi) + \nabla \cdot (\rho_L v) = 0 \qquad (1)$$

207   where $\nabla \cdot$ is the divergence operator, $\rho_L v$ is the fluid mass flux and $\rho_L \phi$ is the mass per unit

208   volume within the matrix. The term ρ_L is the fluid density, ϕ is the matrix porosity and v is

209   the Darcy's flux or velocity, which is defined as

210
$$v = \frac{\kappa}{\mu}(-\nabla P + \rho_L g \nabla z) \qquad (2)$$

211 where κ is the intrinsic permeability of the matrix, μ is the dynamic viscosity, P is the fluid

212 pressure, g is the acceleration due to gravity, and z is the elevation. Substituting equations (2)

213 into (1) and rearranging gives

$$\frac{\partial}{\partial t}(\phi\rho_L)+\nabla\cdot\rho_L\left[\frac{\kappa}{\mu}(-\nabla P+\rho_L g\nabla z)\right]=0 \tag{3}$$

215 Expanding the first term in the equation (3) by expressing the porosity and density as

216 functions of the fluid pressure, and applying the product rule and chain rule of differentiation

217 yields

$$\frac{\partial}{\partial t}(\phi\rho_L)=\phi\frac{\partial\rho_L}{\partial P}\frac{\partial P}{\partial t}+\rho_L\frac{\partial\phi}{\partial P}\frac{\partial P}{\partial t} \tag{4}$$

219 Also, the equation of state (EOS) [36] defines the fluid and matrix compressibilities as

$$C_f=\frac{1}{\rho_L}\frac{\partial\rho_L}{\partial P}, and\, C_m=\frac{1}{\phi}\frac{\partial\phi}{\partial P} \tag{5}$$

221 where C_f and C_m are the fluid and matrix compressibility, respectively. Rearranging

222 equations (5) and inserting the terms into equation (4) yields

$$\frac{\partial}{\partial t}(\phi\rho_L)=\phi\rho_L(C_f+C_m)\frac{\partial P}{\partial t} \tag{6}$$

224 where $\phi(C_f+C_m)$ is defined as linearised storage S, and equation (6) becomes

$$\frac{\partial}{\partial t}(\phi\rho_L)=\rho_L S\frac{\partial P}{\partial t} \tag{7}$$

226 The generalised equation applied for solving problems in porous matrix is obtained by

227 substituting equation (7) into (3)

$$\rho_L S\frac{\partial P}{\partial t}+\nabla\cdot\rho_L\left[\frac{\kappa}{\mu}(-\nabla P+\rho_L g\nabla z)\right]=0 \tag{8}$$

229

230 For the porous matrix with fracture, the conservation of fluid mass within the fracture system

231 is

$$\frac{\partial}{\partial t}(\rho_L\phi_f)+\nabla\cdot(\rho_L v_f)+Q_f+Q_m=0 \tag{9}$$

8

233 The subscript's f and m refer to fracture and matrix, respectively. The term $\rho_L\phi_f$ is mass per

234 unit volume within the fracture, $\rho_L v_f$ is defined as the fluid mass flux within the fracture and

235 ϕ_f is the fracture porosity. The term Q_f denotes the flow from the matrix to the fracture

236 which sometimes referred as the matrix-fracture transfer term. This term describes the flow in

237 the fracture system contains a source term that represents the transport of fluid from the

238 matrix to the fracture that is assumed to be distributed over the entire domain. Two different

239 approaches can be used to determine the matrix-fracture transfer term Q_f, as described in

240 [37-39]. However, in this study, the latter model [40] is chosen and is given as

$$Q_f = -\sum \chi_i(x)\frac{1}{|\Omega_i|}\int_{\Omega_i}\frac{\partial(\phi\rho_L)}{\partial t}dx, \text{ and } \chi_i(x)=\begin{cases}1 & \text{if } x\in\Omega_i,\\0 & \text{otherwise}\end{cases} \qquad (10)$$

241

242 where $|\Omega_i|$ represents the volume of the ith matrix block (i.e. Ω_i) and $\chi_i(x)$ is its

243 characteristic function. On the other hand, the term Q_m is the external sources or sinks of

244 fluid that may be comprised of an injection or production source and sometimes others

245 sources/sinks from the surrounding boundaries. In this case, the expression of Q_m is adopted

246 from [41], by assuming that the sum of the normal components of fluid flow from the matrix

247 block through the boundary cell, given here as

$$Q_m = -\int_{cellboundary}\nabla\cdot\frac{\kappa\rho_L}{\mu}\nabla P\cdot\bar{n}dx \qquad (11)$$

248

249 The Darcy's flux or velocity of the fluid in an equivalent fracture system v_f, defined as

$$v_f = \frac{\kappa_f}{\mu}\left(-\nabla P_f + \rho_L g\nabla z\right) \qquad (12)$$

250

251 in which the fracture permeability κ_f is assumed to obey laminar flow by applying the

252 concept of parallel plate and considering it as a uniform plate, expressed as

$$\kappa_f = \frac{b^2}{12} \qquad (13)$$

253

254 where b is the fracture aperture.

255 Substituting equation (13) into (12), and inserting output back into equation (9), and

256 also replacing the first term in bracket of equation (9) by applying similar expression

9

257 obtained in (7) gives the generalised expression (14) for solving fracture problems in porous

258 media, namely

259
$$\rho_L S_f \frac{\partial P_f}{\partial t} + \nabla \cdot \rho_L \left[\frac{b^2}{12\mu} \left(-\nabla P_f + \rho_L g \nabla z \right) \right] + Q_f + Q_m = 0 \qquad (14)$$

260 However, it is critical to note that solving equations (8) and (14) requires boundary

261 conditions, which are $\rho_L v \cdot n$, and $\rho_L v_f \cdot n$ for the matrix and fracture, respectively. Explicit

262 details are provided in section 3 under the finite element formulations.

263

264 In this paper, local thermal equilibrium heat transport equations between the solid and fluid

265 phases is considered, in which the solid temperature (T_S) is equal to the fluid temperature (

266 T_f) (i.e., $T_S = T_f = T$). Here, it is assumed that heat conduction in the solid and fluid phases

267 occur side-by-side so that there is no net heat transport from one phase to the other.

268 Therefore, the classical Newton's law of cooling is not applicable here, because it is very hard

269 to estimate all the parameters included in the formula. However, it is only possible to apply

270 the formula under laboratory conditions. The governing equation defining heat transport in

271 porous media is the conservation of energy law expressed as

272
$$\frac{\partial}{\partial t} A_E + \nabla \cdot q_E = 0 \qquad (15)$$

273 where A_E is the energy per unit volume is given

274
$$A_E = \phi_S \rho_S c_{\rho,S} T + (1 - \phi_S) \rho_L c_{\rho,L} T = \rho c_\rho T \qquad (16)$$

275 in which ϕ_s and ϕ_L are the solid and liquid volume fraction (porosity), respectively; $c_{\rho,S}$ and

276 $c_{\rho,L}$ are the specific heat capacity for the solid and liquid, respectively; ρ_S is the density of

277 the solid and T is the temperature. Also, q_E is the energy flux given by

278
$$q_E = \rho_L v c_{\rho,L} T + q \qquad (17)$$

279 The coupled contribution of convective heat transfer is giving in the first term of the right-

280 hand side of equation (16) while $q = -\lambda \nabla T$ is the input of conductive heat transfer referred

281 as the Fourier's law, where λ is the effective thermal conductivity of both the solid and

282 liquid phases expressed as $\lambda = \phi_S \lambda_S + (1 - \phi_S) \lambda_L$, in which λ_S is the solid thermal

283 conductivity and λ_L is liquid thermal conductivity. Substituting equations (16) and (17) with

284 their derivatives into equation (15) yields the general expression for solving heat transport in

285 the porous matrix as, i.e.

$$286 \qquad \rho c_\rho \frac{\partial T}{\partial t} + \nabla \cdot \left(\rho_L v c_{\rho,L} T - \lambda \nabla T \right) = 0 \qquad (18)$$

287 Similarly, the conservation of fracture energy within a matrix block is given by

$$288 \qquad \frac{\partial}{\partial t} A_{f,E} + \nabla \cdot q_{f,E} + Q_{f,E} + Q_{m,E} = 0 \qquad (19)$$

$$289 \qquad \rho c_\rho \frac{\partial T}{\partial t} + \nabla \cdot \left(\rho_L v_f c_{\rho,L} T - \lambda_f \nabla T \right) + Q_{f,E} + Q_{m,E} = 0 \qquad (20)$$

290 where $Q_{f,E}$ and $Q_{m,E}$ are the energy sources/sinks for the fracture and matrix systems, $A_{f,E}$ is

291 the energy per unit volume within the fracture expressed similarly to equation (17), $q_{f,E}$ is

292 the energy flux within the fracture. However, by putting into consideration it obeys the theory

293 of parallel plate for fracture opening. Expanding and solving for the sub-equations within

294 (19) as presented in the matrix section of the heat transport (equation (15-18)) on fractures,

295 yields the general expression for heat transport in fractures given in equation (20).

296

3. Finite element formulation for coupled TH model

298 This section presents the application of finite element method (FEM) to coupled TH

299 problems in fully saturated and fractured porous media. The use of the coupled procedures

300 and the partial differential equations (PDE) displayed above is incorporated in developing the

301 FEM model. It is essential to define the initial and boundary conditions (BC) of the problem

302 before formulating the finite element solutions. The initial conditions specify the field

303 pressures and temperatures at $t=0$, i.e.

$$304 \qquad P = P_0, T = T_0 \ in \ \Omega \ and \ on \ \Gamma \qquad (21)$$

305 where Ω is the domain of interest and Γ is the boundary.

306

307 In the case of BC's, they can be defined in two different kind that include the Dirichlet BC Γ

308 , and the Neumann BC Γ^q. For the fluid flow, the Dirichlet pressure BC can be imposed as a

309 constant value either at the injection/extraction wellbore boundaries, or far-field boundaries

310 as

$$311 \qquad P = \hat{P} \ on \ \Gamma_P \qquad (22)$$

11

312 The Neumann BC for the fluid flow can be prescribed as a mass flux normal to the boundary

313 surface or at the injection/extraction wellbore boundaries as

$$q_P = \rho_L \frac{\kappa}{\mu} \left(-\nabla P + \rho_L g \nabla z \right)^T \cdot n \quad on \ \Gamma_P^q \tag{23}$$

315 where n is normal to the boundary. Also, sometimes it can be employed as no-flow

316 boundaries by setting equation (23) to zero.

317 In the case of heat transfer, the Dirichlet temperature BC can be imposed as a value (in the

318 case of isothermal condition) at the injection wellbore boundary or far-field boundaries as

$$T = \hat{T} \ on \ \Gamma_T \tag{24}$$

320 The Neumann BC for the heat transfer can be imposed as a heat flux normal to a boundary or

321 as an injection wellbore boundary (in the case of non-isothermal condition), which is given as

$$q_T = \left(-\lambda \nabla T + \rho_L C_{P,L} v T \right)^T \cdot n \quad on \ \Gamma_T^q \tag{25}$$

323 In addition, the Neumann BC can also be prescribed as heat flux value at the heat outflow BC

324 in the production wellbore boundary using the expression for the convective heat transfer as

325 $q_T = \rho_L v.n$.

326

327 The boundary value problem presented in the previous section, for example equations (8) is

328 written as

$$X(u) = B(u) + J = 0 \ in \ \Omega \tag{26}$$

$$Y(u) = D(u) + K = 0 \ on \ \Gamma \tag{27}$$

331 where X and Y are the derivate of differential operators, B and D are appropriate differential

332 operators, and J and K are known functions independent of the field variable u, which are the

333 exact solution of the boundary value problem. By considering the integral statement

$$\int_\Omega \varphi^T X(u) d\Omega + \int_\Gamma \hat{\varphi}^T Y(u) d\Gamma = 0 \tag{28}$$

335 is satisfied for a set of arbitrary functions φ and $\hat{\varphi}$, which is equivalent to satisfying

336 differential equation (26) and (27). If equations (26) and (27) are satisfied, then equation (28)

337 is true. An approximate solution is sought in the class of functions $\hat{u}$, namely

338
$$u \approx \hat{u} = \sum_{i}^{j} N_i a_i = N a \tag{29}$$

339 which is obtained by introducing a set of trial or shape functions N_i regarding the

340 coordinates; and a_i are the unknown values defined at points (nodes) in the domain Ω and

341 the boundary Γ. If equation (29) is substituted into (26) and (27), they remain an error, or

342 residual, i.e.

343
$$R = R_{\Omega} + R_{\Gamma} = X\left(\hat{u}\right) + Y\left(\hat{u}\right) \tag{30}$$

344 To minimise the residual over the whole domain and the boundary, a zero value for an

345 appropriate number of integrals of the error over Ω and Γ, weighted by weighting functions w

346 and $\hat{w}$, is sought, which is called the weighted residual method (WRM) [42], namely

347
$$\int_{\Omega} w^T X(\hat{u}) d\Omega + \int_{\Gamma} \hat{w}^T Y(\hat{u}) d\Gamma = 0 \tag{31}$$

348 Expression (31) is an approximation to the integral defined in equation (28) and results in a

349 set of equations for the unknowns a_i, which can be written as

350
$$Ka = f \tag{32}$$

351 where K is the stiffness matrix, a is the unknown field; and f is the load matrix defined as

352
$$K_{ij} = \sum_{e=1}^{m} K_{ij}^e \qquad f_i = \sum_{e=1}^{m} f_i^e \tag{33}$$

353 where K^e is known as the stiffness matrix for the eth element and f^e is the boundary flux

354 for the eth element, and the derivative of the differential operators X and Y must be

355 continuous over the domain. The WRM, that is equation (31), is now applied to mass

356 conservation equations (8) and its Neumann boundary condition equation (21), which yields

357
$$\int_{\Omega} w^T \left\{ \nabla^T \left[\frac{\kappa}{\mu} \left(-\nabla P + \rho_L g \nabla z \right) \right] \right\} d\Omega + \int_{\Omega} w^T S \frac{\partial P}{\partial t} d\Omega + \int_{\Gamma_p^q} \hat{w}^T \left[\frac{\kappa}{\mu} \left(-\nabla P + \rho_L g \nabla z \right)^T \cdot n - \frac{q_p}{\rho_L} \right] \cdot d\Gamma = 0$$

358
$$\tag{34}$$

359 By limiting the choice of the weighting functions [42], such that

360
$$w = 0 \qquad on \qquad \Gamma_P \tag{35}$$

361
$$\hat{w} = -w \qquad on \qquad \Gamma_p^q \tag{36}$$

13

362 Applying the Green's theorem on the first portion of equation (34) and incorporating

363 equations (35) and (36) into it, gives

$$364 \quad \int_{\Omega}\left[-(w\nabla)^T\left(-\frac{\kappa}{\mu}\nabla P+\frac{\kappa}{\mu}\rho_L g\nabla z\right)\right]d\Omega +\int_{\Omega}w^T S\frac{\partial P}{\partial t}d\Omega+\int_{\Gamma_p^q}w^T\frac{q_p}{\rho_L}d\Gamma=0 \qquad (37)$$

365 The same procedure applied to the fluid flow when used in the energy balance equation in

366 (18), and its Neumann boundary conditions in (24) by limiting the choice of weighting

367 functions, such that

$$368 \qquad w=0 \quad on \qquad \Gamma_T \qquad (38)$$

$$369 \qquad \hat{w}=-w \quad on \qquad \Gamma_T^q \qquad (39)$$

370 also applying the Green's theorem to the second portion of equation (18), yields

$$371 \quad \int_{\Omega}w^T c_\rho \rho\frac{\partial T}{\partial t}d\Omega+\int_{\Omega}w\rho_L v c_{\rho,L}\cdot\nabla T\,d\Omega+\int_{\Omega}(\nabla w)^T\cdot(-\lambda\nabla T)d\Omega+\int_{\Gamma_T^q}w^T q^T d\Gamma=0 \qquad (40)$$

372 Equations (37) and (40) are the weak formulation (weak form) of the governing equations

373 presented in section 2.2, and by applying the Galerkin FEM to discretise the weak form

374 spatially [43]. The state variables are expressed regarding the nodal values and shape

375 functions as

$$376 \qquad P=N_P\hat{P}\,;\,T=N_T\hat{T} \qquad (41)$$

377 where $\hat{P}$ and $\hat{T}$ are the scalars of the nodal values of the pressures and temperature, N_P and

378 N_T are shape functions. For a coarse tetrahedral element of 3D problem, they can be

379 represented as

$$380 \qquad N_P=[N_{P1}\;N_{P2}\;N_{P3}\;N_{P4}],\,N_{Pi}=diagonal\{N_{Pi}\;N_{Pi}\;N_{Pi}\;N_{Pi}\},\,i=1,4$$

$$381 \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (42)$$

$$382 \qquad N_T=[N_{T1}\;N_{T2}\;N_{T3}\;N_{T4}],\,N_{Ti}=diagonal\{N_{Ti}\;N_{Ti}\;N_{Ti}\;N_{Ti}\},\,i=1,4 \qquad (43)$$

383 By the introduction of equation (41) into equations (37) and (40); then applying the Galerkin

384 FEM, and replacing the weighting functions w and $\hat{w}$ with the corresponding shape

385 functions N_P and N_T, gives

386
$$\int_{\Omega}\left[(\nabla N_P)^T \frac{\kappa}{\mu}\nabla N_P \hat{P} - (\nabla N_P)^T \frac{\kappa}{\mu}\rho_L g \nabla z\right]d\Omega + \int_{\Omega} N_P^T SN_P \frac{\partial \hat{P}}{\partial t}d\Omega + \int_{\Gamma_p^q} N_P^T \frac{q_p}{\rho_L}d\Gamma = 0 \quad (44)$$

387
$$\int_{\Omega} N_T^T c_\rho \rho N^T \frac{\partial \hat{T}}{\partial t}d\Omega + \int_{\Omega}\left[(N_T^T c_{\rho,L} q_m \cdot \nabla N_T)\hat{T}\right]d\Omega + \int_{\Omega}\nabla N_T^T(-\lambda\nabla N_T)\hat{T}d\Omega + \int_{\Gamma_T^q} N_T^T q^T d\Gamma = 0$$

388
$$(45)$$

389   Further discretising equations (44) and (45) gives

390
$$K_P = \int_{\Omega} N_P^T SN_P d\Omega \tag{46}$$

391
$$M_P(T) = \int_{\Omega}(\nabla N_P)^T \frac{\kappa}{\mu}\nabla N_P d\Omega \tag{47}$$

392
$$f^P(T) = \int_{\Omega}(\nabla N_P)^T \frac{\kappa}{\mu}\rho_L g d\Omega - \int_{\Gamma} N_P^T \frac{q_p}{\rho_L}d\Gamma \tag{48}$$

393
$$K_T = \int_{\Omega} N_T^T c_\rho \rho N_T d\Omega \tag{49}$$

394
$$M_T(P) = \int_{\Omega}\left\{N_T^T(\rho_L v c_{\rho,L} \cdot \nabla N_T) + \nabla N_T^T(-\lambda\nabla N_T)\right\}d\Omega \tag{50}$$

395
$$f^T(P) = -\int_{\Gamma_T^q} N_T^T q_T d\Gamma \tag{51}$$

396   where K_P is the compressibility matrix; M_p is the permeability matrix; f^P is the load

397   matrix for the fluid flow process; K_T is the capacity matrix; M_T is the conductivity matrix;

398   and f^T is the load matrix for the heat transport. The staggered method is considered in

399   coupling terms of the equations (44) and (45). By using equations (46) - (51), equations (44)

400   and (45) are written as

401
$$M_p(T)\hat{P} + K_P \frac{\partial \hat{P}}{\partial t} = f^P(T) \tag{52}$$

402
$$M_T(P)\hat{T} + K_T \frac{\partial \hat{T}}{\partial t} = f^T(P) \tag{53}$$

403   The above equations are represented in matrix form as

404
$$\begin{bmatrix} M_P(T) & 0 \\ 0 & M_T(P) \end{bmatrix} \begin{Bmatrix} \hat{P} \\ \hat{T} \end{Bmatrix} + \begin{bmatrix} K_P & 0 \\ 0 & K_T \end{bmatrix} \frac{\partial}{\partial t} \begin{Bmatrix} \hat{P} \\ \hat{T} \end{Bmatrix} = \begin{Bmatrix} f^P(T) \\ f^T(P) \end{Bmatrix}$$ (54)

405 Similarly, by applying the procedure of FEM solution obtained in (52) and (53) to the

406 fracture equations in (14) and (20), yields

407
$$M_{p,f}(T)\hat{P}_f + K_{P,f}\frac{\partial \hat{P}_f}{\partial t} = f^{P,f}(T)$$ (55)

408
$$M_{T,f}(P)\hat{T}_f + K_{T,f}\frac{\partial \hat{T}_f}{\partial t} = f^{T,f}(P)$$ (56)

409 where $K_{P,f}$ is the compressibility matrix for the fracture; $M_{p,f}$ is the permeability matrix

410 for the fracture; $f^{P,f}$ is the load matrix for the fracture flow; $K_{T,f}$ is the capacity matrix for

411 the fracture; $M_{T,f}$ is the conductivity matrix for the fracture; and $f^{T,f}$ is the load matrix for

412 the fracture heat transport.

413

414 **4. Solution procedure and verification**

415 In this study, the fluid flow and the heat transport field equations are considered as

416 independent systems for the pressure, and thermal multi-coupling mathematical model. The

417 staggered method equation is used with the Galerkin method (finite element discrete method)

418 in the geometry domain to obtain the numerical solution of the coupling iteration problems.

419 Then, by applying the finite difference method (FDM) in the time domain as discussed in

420 [44], to obtain the solution of the coupled equations (52) and (53), by

421
$$M_p(T)[P_{t+1} - P_t]/\Delta t + K_P[\theta P_{t+1} + (1-\theta)P_t] = f^P(T)$$ (57)

422
$$M_T(P)[T_{t+1} - T_t]/\Delta t + K_T[\theta T_{t+1} + (1-\theta)T_t] = f^T(P)$$ (58)

423 For the discrete fracture equations (55) and (56), the solution is obtained from

424
$$M_{p,f}(T)\left[P_{f_{t+1}} - P_{f_t}\right]/\Delta t + K_{P,f}\left[\theta P_{f_{t+1}} + (1-\theta)P_{f_t}\right] = f^{P,f}(T)$$ (59)

425
$$M_{T,f}(P)\left[T_{f_{t+1}} - T_{f_t}\right]/\Delta t + K_{T,f}\left[\theta T_{f_{t+1}} + (1-\theta)T_{f_t}\right] = f^{T,f}(P)$$ (60)

426 where t and $t+1$ indicates the previous and current time steps, respectively; Δt is the time

427 step size; θ is the relaxation parameter with limit $0 \le \theta \le 1$. The FDM is employed to

428 calculate parameter by time step, and the specified initial time step with an acceleration factor

429 of 1. It is verified by repeated calculations to be stable and reliable for the computed results.

430 The solution of the TH coupled nonlinear model is attained by using a mixture of Newton-

431 Raphson and Picard schemes [45].

432

433 The convergence termination criterion employed for the nonlinear iterations in the study is

434 the weighted Euclidean norm, which terminates the iteration solutions when the relative

435 tolerance exceeds the relative error computed [46], given as

436
$$Error = \sqrt{\frac{1}{N_F}} \sqrt{\sum_{j=1}^{N_F} \frac{1}{N_j} \sum_{i=1}^{N_j} \left(\frac{\left| E_{i,j} \right|}{W_{i,j}} \right)^2} \qquad (61)$$

437 where N_F is the number of fields and N_j is the number of degrees of freedom in field j.

438 The double subscript denotes the degree of freedom index i and j component. E is the

439 estimated error in the scalar, $W_{i,j} = \max \left(\left| U_{i,j} \right|, S_j \right)$, $U_{i,j}$ is the current approximation to the

440 solution scalar, and S_j is a scale factor for which the program determines the scaling process.

441

442 To verify the solution capabilities described, a simple two-dimensional (2D) model is

443 analysed by implementing the model in COMSOL with a link to MATLAB (COMMAT).

444 The verification carried out here is the disturbance caused by the presence of fracture in a

445 porous medium with a uniform flow. A similar problem was analysed by Strack as reported

446 in [47], where an analytical model for this issue is derived as the potential flow. In this study,

447 the model verified reported in [47] is used to verify the proposed model. Figure 2 presents the

448 2D model of the problem with a 1D fracture as a hydraulic conduit. Fluid is injected and

449 extracted on the left P_{in} and right P_{out} sides of the model, respectively. On the other hand, the

450 top and bottom represent no flow boundaries $\nabla P \cdot n = 0$. The fracture is 2 m in length with an

451 orientation angle of $45°$, and the flow is assumed to be laminar along its surface, and the

452 shape is assumed to have normal displacements at the sides, as used in the case of a

453 pressurised crack in an elastic medium, expressed as

454
$$b = b_{\max} \sqrt{1 - x'^2} \qquad (62)$$

455 where $b_{\max}$ is the aperture at the centre and x' is the normalised local coordinate systems.

456 Table 1[47] presents other parameters used in the numerical simulation of the porous media.

457

17

458   The results obtained are grouped into two sets. The first set of the results is the pressure

459   distribution in the vicinity of the fracture and its flow pattern. Figure 3(a) presents the

460   pressure distribution of the previously reported results [47], while Figure 3(b) depicts the

461   numerical simulation carried out by the developed FE model. As observed, the results are in

462   good agreement between the previous model and the FE model formulated in this work. The

463   second set of the result verified in this study is the pressure profile along a diagonal line from

464   the bottom-left passing through the fracture to the top-right of the geometry. Figure 4

465   presents the results of both the previous work and the current FE model. As can be seen, the

466   graph shows a good agreement between the two solutions. Therefore, the capability of the

467   newly developed FE model is verified using a related problem applicable to porous medium

468   modelling.

469

470   **5. Geothermal reservoir case study**

471   Figure 5(a), shows a schematic representation of the reservoir geometry for Soultz

472   geothermal system (i.e. half part of the reservoir), it depicts a deep geothermal system with

473   800 m × 800 m × 5000 m deep. The reservoir is assumed to be 300 m in thickness and is

474   located at about 4.5 km below the ground surface, and bounded at top and bottom by

475   impermeable layers of granite. The top and bottom layers in Figure 5(a) represent the

476   overburden and underburden, and the middle layer in-between display the reservoir. The

477   wellbores constitute a doublet (single injector and producer) 11 m apart at the ground surface,

478   and 600 m apart laterally at the reservoir level as given in the Soultz geothermal system.

479   Also, the injection well is positioned 100 m and 400 m in the horizontal and vertical

480   distances, while the production well is located 700 m and 400 m in both the x and y

481   coordinates as shown in Figure 5(a). Both the injector and producer are inclined to angles of

482   10° and -10°, respectively.

483   Moreover, a single fracture intersects the reservoir through the overburden down to

484   the underburden layer as in Figure 5(a). The fracture dips at an angle of 60°, which is a

485   normal faulting regime to be precise with an approximated aperture of 50 mm.

486   Table 2 presents the petro-physical properties and physical parameters used in the

487   numerical model [4]. The material properties are extracted from the Soultz geothermal

488   system as in [4]. For the fluid material properties, expressions presented by Holzbecher [48]

489   are employed in the study, which includes density, viscosity, thermal conductivity, and heat

490   capacity. Details of the properties can be found [48]. The system at initial pressure is

491   hydrostatic throughout the model, and the initial temperature (T_{init}) is given as

492     $T_{init} = T_{surf} - 0.03[K/m] \times (-z)$, where T_{surf} is surface temperature and is assumed to be

493   283.15 K. The boundary condition applied for the temperature is 40°C (fluid injection

494   temperature), and for the hydraulic process is 30 l/s (injection flow rate). Moreover, explicit

495   details of the boundary conditions used in the geothermal reservoir model are provided in

496   Table 3.

497

5.1 Mesh and solution convergence

499   In this model, the meshes are divided into three-dimensional (3-D) tetrahedral (for the matrix

500   block), two-dimensional (2-D) triangular (for the fracture), and one-dimensional (1-D) line

501   (wells) elements, respectively. Figure 5(b) showed the mesh system that connects finer and

502   fine grids in the calculation to reduce the impact of boundary effects. The implementation of

503   the finer meshes on the wellbores is to increase the calculation accuracy; and also strengthens

504   the calculating intensity and workload. Therefore, the mesh division method not only

505   increases calculation accuracy but also eradicate the deviation caused by inappropriately

506   selected boundary conditions, which have some significant effect on the long-term extracting

507   vicinity and heat recovery after extraction.

508   The mesh convergence study of the proposed geothermal reservoir has been examined

509   to explore the model computational efficiency in handling the cases of various structural

510   variations mentioned. Five mesh sizes are utilised: M1=20463, M2=39925, M3=68780,

511   M4=189774, and M5=747838 starting from coarse to extra fine. Figure 5(c) shows the results

512   representing temperature profiles along the production wellbore for all meshes. It is also

513   evident that there is no significant difference in the results between the five meshes, though

514   the results of the coarse and normal meshes, M1 and M2, are less accurate. However, it

515   manifests no numerical oscillations. Notwithstanding, it can be deduced that the model

516   converged at M3 mesh. The CPU time for 55-time steps are M1=108 s, M2=201 s, M3=363

517   s, M4 = 1083 s, and M5=10177 s in an Intel(R) Core(TM) i5-5200U CPU @ 2.20 GHz, 2

518   cores.

519   To overcome numerical errors in the FEM solution, it is essential to check the

520   convergence criterion for the solution. The convergence criterion in equation (58) is

521   employed for the error estimation during solution iterations for the geothermal reservoir

522   modelling. Figure 5(d) shows the number of iterations and the corresponding errors. The

523   result indicates that an average of five iterations is sufficient to obtain an accurate solution.

524

5.2 Effect of cold water front

For the matrix block, the analysis is performed with an injection rate of 20 l/s, an injection temperature of 40°C, and a well lateral distance of 600 m. The temperature distribution study confirms the activity of the coupled processes (between the thermal and hydraulic properties) because the heat transfer mechanism is found to obey convective-dominated behaviour due to the strong coupling. Figure 6(a) shows the temperature at time $t=0$, which happens to be same as the initial temperature of the system, affirming that the effect of the Dirichlet BC is yet to commence. However, there was a regional groundwater flow induced by the gradient from top to bottom existing before the injection. Figure 6(b) shows temperature distribution results after 15 years of simulation, with some part of the matrix experiencing the cooling effect of the injected fluid temperature. The process continues to propagate until the end of the simulation (30 years), as shown in Figure 6(c).

537

To investigate the effect of cold water front in the reservoir, the cold water, at a temperature of 40°C, is injected at a rate of 20 l/s through two different injections well scenarios; one is situated 100 m and the other 50 m away from the left end. Hot water is extracted by two production wells; the first is located at 700 m, and the second at 750 m from the left end, as shown in Figure 7(a-f). The effect of the cold water front propagation is examined after 1, 10 and 30 years of simulation for 600 m and 700 m lateral well spacing's as shown in Figures 7(a-f). In all the cases analysed, it was observed that the injected fluid creates a cold front near the injection well, which later evolves through the reservoir domain because the injected fluid is cooler than the geothermal reservoir.

Also, it should be noticed that the temperatures of the right boundaries are kept equal to the initial temperature of the reservoir until the cold-water front reaches the boundary, and after that, the temperature of the boundary starts increasing as presented in Figures 7(c-f).

550

5.3 Parametric studies

Developing a design model efficient in assessing the lifespan of a geothermal reservoir requires the understanding of some key control parameters during exploration and exploitation. In this study, three basic human control parameters are analysed by varying one parameter at a time using the OFAT approach, while keeping the rest at a constant based on the Soultz geothermal case, as presented in Section 5.1. The human control parameters studied here are injection flow rate (discharge), injection fluid temperature, and lateral well

558 spacing. Studying these three key parameters provides a preliminary evaluation of the effects

559 of reservoir parameters on the commercial applicability of enhanced geothermal system

560 utilisation. The effects of the parameters are assessed based on the productivity of the

561 reservoir during the exploitation period of 30 years. The geothermal reservoir conditions

562 specified are simulated to acquire the anticipated variations in temperature, pressure, and

563 thermal energy over 30 years. The parameters studied vary over the range of values that are

564 acceptable for the geothermal exploitation of the Soultz site.

565   In a nutshell, the temperature of the reservoir was monitored using the parameters given

566 above at production wellhead with a simulation period of 30 years.

567

568 5.3.1 Effect of injection flow rate

569 The injection flow rate is one of the human control parameters that have a direct effect on the

570 reservoir lifespan. In order to quantify the effect, six cases were analysed. These cases range

571 from 20 to 70 l/s with an incremental step of 10 l/s. Each of the cases is then studied under

572 different scenarios of injection temperature and well separation distances of 40°C and 50°C,

573 and 600 and 700 m, respectively. All other parameters remain constant as explained before.

574 Figure 8 shows the production wellbore temperature curves for the effect of various injection

575 flow rates. Figures 8(a) and 8(b) present the temperature history at the production well for the

576 scenarios of 40°C and 50°C under the effect of 600 m well distance, while Figures 8(c) and

577 8(d) show the production temperature for the same scenarios of injection temperature above

578 with 700 m well spacing.

579   Figure 8a shows the temperature curves at the production wellbore for the different

580 injection flow rates under a constant injection temperature of 40°C and lateral well spacing of

581 600 m. As seen, the temperature curves differ for the various cases; the higher rate declines

582 earlier than the lower rate. For example, the 70 l/s injection flow rate starts to decline just

583 after 0.8 years of simulation, whereas the 20 l/s injection flow rate begins to decrease after

584 approximately 2.6 years. As a result, the produced temperature is higher when the injection

585 flow rate is lower, and vice versa. The reason for the variation is that the greater the injection

586 flow rate, the faster the cooling of the reservoir is, and the lower the flow rate, the slower the

587 cooling becomes. The same trend is observed in Figure 8b when the injection fluid

588 temperature is changed to 50°C in similar operational scenarios as in Figure 8a, with slight

589 shifts in the production temperature. It is noted that the increase in the injection fluid

590 temperature to 50°C has a lesser effect on the produced temperature in those cases.

591   Figure 8c presents the temperature breakthrough curves at the production well for

592 different injection flow rates under the influence of 40°C injection temperature and 700 m

593 lateral well spacing. In these cases, the earliest decline starts after 1.6 years of simulation for

594 the highest injection rate (i.e. 70 l/s) and 5.6 years in the case of lowest injection flow rate (20

595 l/s). Furthermore, the decrease in the production temperature at the extraction well during the

596 30-year simulation is 8.31°C and 8.93°C for the lowest and highest injection flow rates,

597 respectively. The low decline is recorded in these cases because the lateral well spacing

598 between the injector and the producer is larger, so the production well bore is not affected

599 much by the reservoir cooling after a 30-year simulation. Likewise, the same response is

600 observed in Figure 8d with slight changes in the production temperature due to the increase in

601 the injection fluid temperature.

602 In all the cases and scenarios, it is observed that as the injection rate increases, the reservoir

603 temperature decreases rapidly. Moreover, the injection temperature and the well spacing also

604 have some effects on the production rate. The maximum temperature is achieved when the

605 injection temperature is at its lowest and well spacing is at its largest, then combined with the

606 lower injection rate as shown in the figures presented.

607

608 5.3.2 Effect of injection fluid temperature

609 The surrounding rock supplies some amount of the heat enthalpy conducted in the reservoir;

610 however, the injected fluid temperature governs the major heat enthalpy added into the

611 reservoir due to the convective heat transfer. In this study, six cases of fluid injection

612 temperature are investigated. These cases range from 10°C to 60°C with an incremental step

613 of 10°C, and each of the cases is additionally studied under varying scenarios of pumping

614 rates of 20 l/s and 30 l/s, and well lateral spacing of 600 m and 700 m. Figure 9 shows the

615 temperature production curves for the effect of injection fluid temperatures. Figures 9(a) and

616 9(b) present the produced temperature for the scenarios of 20 l/s and 30 l/s following the

617 influence of 600 m well spacing. Figure 9a shows the breakthrough temperature curves at the

618 production well; the temperature curves begin to decline after approximately 1.8 years of

619 simulation with a temperature of 150.93°C in almost all cases. After approximately 10-12

620 years of simulation, a little gap is observed between the different injection temperature

621 scenarios, and it continues to widen till the 30-year simulation period. The reason for these

622 similarities in the production temperature breakthrough curves is that the effect of reservoir

623 cooling started in approximately the same period in all cases. Similarly, Figure 9b shows the

624 production breakthrough curves for the different injection temperature scenarios when

combined with 30 l/s injection flow rate and 600 m lateral well spacing. As can be seen, the production temperature trend is similar to Figure 9a with little difference; in this case, the decline started after approximately 1.2 years of simulation (earlier than the former scenario) with a temperature of 150.93°C in almost all cases. Also, in this scenario, some little deviations are seen from approximately 8.5-10 years, and these continue to grow until the end of the simulation. The idea behind the earlier variation between the different cases is the increase in the injection flow rate to 30 l/s, which causes the fast cooling of the reservoir.

Similarly, Figures 9(c) and 9(d) show the production temperatures using the same injected rate with 700 m well spacing. Figure 9c shows the temperature curves at the production wellbore for different cases of the injection fluid temperature under the influences of 20 l/s injection flow rate and 700 m lateral well spacing. As seen, the temperature breakthrough curves have a similar trend except in the case of the 10°C injection fluid temperature rate. The production temperature began to decline after approximately 4.2 years of the simulation cases of 20°C to 60°C, while in the case of the 10°C injection scenario, it began at approximately three years of simulation. The temperatures at the decline stages are 150.73°C and 150.74°C, in both the former and the latter, respectively. As the simulation continues, the breakthrough curve for the 10°C injection cases shows a sudden transition change from lower to higher between 8.8 and 9.2 simulation period and maintains a regular pattern till the end of the simulation, whereas the other cases maintain the same decline pattern. The reason for the variation of the 10°C case with remaining scenarios is that after equilibrium is reached for cooling the higher injection rate propagates faster to the production wellbore than the former. Likewise, Figure 9d shows similar breakthrough curves as in Figure 9c with little difference concerning the starting period of decline and the transition phases of the 10°C injection due to the increase in the injection flow rate. Apart from those points, all other trend remains the same.

In all the scenarios studied, it is observed that there were no significant changes in the produced temperature from the reservoir.

5.3.3 Effect of lateral well spacing

To overcome the cold water effect and water losses that result from reduced productivity of reservoir wells, they must be placed at an optimum distance from each other. The choice of place will depend on the geological formation and production flow rates. Larger well spacing results in greater reservoir sizes and vice versa. However, with large spaces between wells, fluid losses are likely to be a significant problem, and with small spaces, the fluid losses are

negligible. Therefore, the well spacing must be optimised to achieve the maximum possible reservoir size and production flow rate. In this work, six scenarios of well lateral spacing are examined. The spaces between the reservoir wells are chosen as 400, 500, 600, 650, 700, and 750 metres long, respectively. Also, in each of the scenarios, different injection rates, of 20 l/s and 30 l/s, and injection fluid temperatures, of 30ºC and 40ºC, are analysed. Figure 10 presents the temperature curve at the production wellbore for the effect of lateral well spacing. Figures 10(a) and 10(b) show the produced temperature in the cases where 20 l/s were injected at 30ºC and 40ºC, respectively while Figures 10(c) and 10(d) show the production temperature when 30 l/s were injected at 30ºC and 40ºC respectively.

Figure 10a shows the temperature breakthrough curve at the extraction well for the different scenarios of the lateral well spacing when combined with an injection fluid temperature of 30°C and injection flow rate of 20 l/s. As can be seen, the further the spacing, the higher the produced temperature, and vice versa. For instance, in the case of 400 m lateral well spacing, the temperature begins to decrease just after 0.8 years of the simulation period. Concerning the 700 m lateral wellbore spacing, the decline starts after approximately 9.4 years. Moreover, after a simulation period of 30 years, the produced temperature for the closer well spacing (i.e., 400 m) was approximately 116°C, and the largest spacing (750 m) is 145°C, which amounted to a 30°C temperature difference between the two cases. The reason for this significant deviation between the scenarios is the closer the spacing, the higher the impact of cold water propagation on the production wellbore, and vice versa. Likewise, a similar trend of Figure 10a is seen in Figures 10b-d, with slight sights in the temperature breakthrough curves due to the different injection fluid temperatures and flow rates employed.

In all the scenarios, it is observed that as the lateral well spacing increases, the production temperature rises.

5.4 Energy extraction rates

The model adopted in this investigation is the one proposed by Kruger [49][50] for the calculations of the total energy extraction in all the scenarios and cases, expressed here as

$$\Delta E_i = Q_i C_{\rho,L} \Delta T_i \tag{63}$$

where ΔE_i is the annual energy produced in the ith year, Q_i is the total production flowrate in the ith year, $C_{\rho,L}$ is the specific heat capacity of the circulated fluid, and ΔT_i is the

691 temperature difference between the extracted and injected fluid in the ith year. The total

692 energy produced from the system for 30 years of extraction can be written as

693
$$\Delta E = \sum_{i=1}^{30} \Delta E_i \tag{64}$$

694

695 Based on the limitations of the injection flow rate range and other parameter combinations

696 studied in this work using the OFAT approach, the results show that as the injection flow rate

697 increases, the energy extraction rate increases with a positive linear relationship as indicated

698 in Figure 11, which shows that the injection rate increase affects the production output.

699 Figure 11 also shows the influence of well spacing and the effect of injection fluid

700 temperature on the energy extraction rate when combined with injection scenarios. The

701 results revealed that wider well spacing coupled with lower fluid injection temperatures

702 yields higher energy when compared to larger spacing with higher rates.

703

704 As for the effect of fluid injection temperature on the energy extraction rate, Figure 12 shows

705 an inverse relationship between fluid injection temperature and the energy extraction rate. As

706 the fluid injection temperature rises, the energy extracted from the reservoir declines

707 significantly, because ΔT_i reduces with the rising fluid injection temperature. Hence, the

708 reservoir lifespan is prolonged for the reproduction of hot water with the same temperature.

709 Also, these cases are further investigated with different well spacing and fluid injection rates,

710 and the results showed that larger well spacing linked with a higher injection fluid rate

711 generates greater extraction energy in comparison to other combinations.

712

713 Figure 13 presents the effect of well spacing on the extraction energy of the reservoir. In all

714 the scenarios analysed, it is observed that, as the well spacing increased, the energy extracted

715 from the system increases rapidly due to the cold water front propagation affecting the closer

716 wells earlier than the further ones. The increase shown in Figure 13 occurs in a nonlinear

717 manner with two different gradients; the gradient of the first two spacing is steeper than the

718 remaining ones because the latter spacing have similar resistance to the cold water front.

719

720 **6. Conclusions**

721 In this paper, a three-dimensional numerical model for coupled thermo-hydraulic processes in

722 a heterogeneous fractured geothermal reservoir overlain and underlain by impermeable layers

723 is proposed. The primary objective is to examine the effect of human control parameters on

724 geothermal reservoir productivity. A verification study is first performed to test the capability

725 of the solver, and the outcomes achieved are in agreement with the existing solvers. Also

726 presented in the studies is the effect of cold water in the matrix block and reservoirs before

727 conducting the main analyses on the human control parameters. An extensive parametric

728 analysis is investigated for a broad range of the parameters and operational scenarios. The

729 injection flow rate has a significant effect on energy production as the rate increases, the

730 energy extraction rate rises, and the system lifetime decreases. Thus, higher injection flow

731 rate is a positive factor in production and, at the same time, a negative factor on reservoir

732 lifespan. In the case of fluid injection temperature, the effect is less significant to production

733 because, as the injection temperature increases, the extraction energy declines rapidly and the

734 reservoir lifespan increases. The well lateral spacing also behaves similarly to the injection

735 flow rate, but it is not as effective as the injection flow rate regarding energy extraction and

736 provides a longer reservoir lifetime than the former.

737 The developed model gives in-depth insight to stakeholders and reservoir engineers

738 with regard to the key parameters to control during exploration and exploitation. The results

739 presented can be effectively employed in the design of human control parameters in a

740 geothermal reservoir system. The model can also serve as a reference solution to other

741 complex interactions encountered in reservoir simulations.

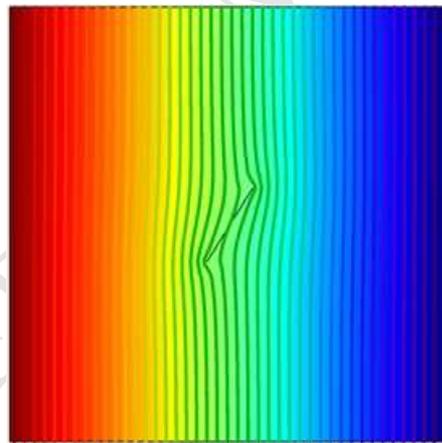

Figure 3(b): Pressure distribution for the current FE model

Figure 3: Verification of the proposed procedure with the existing model in [42]
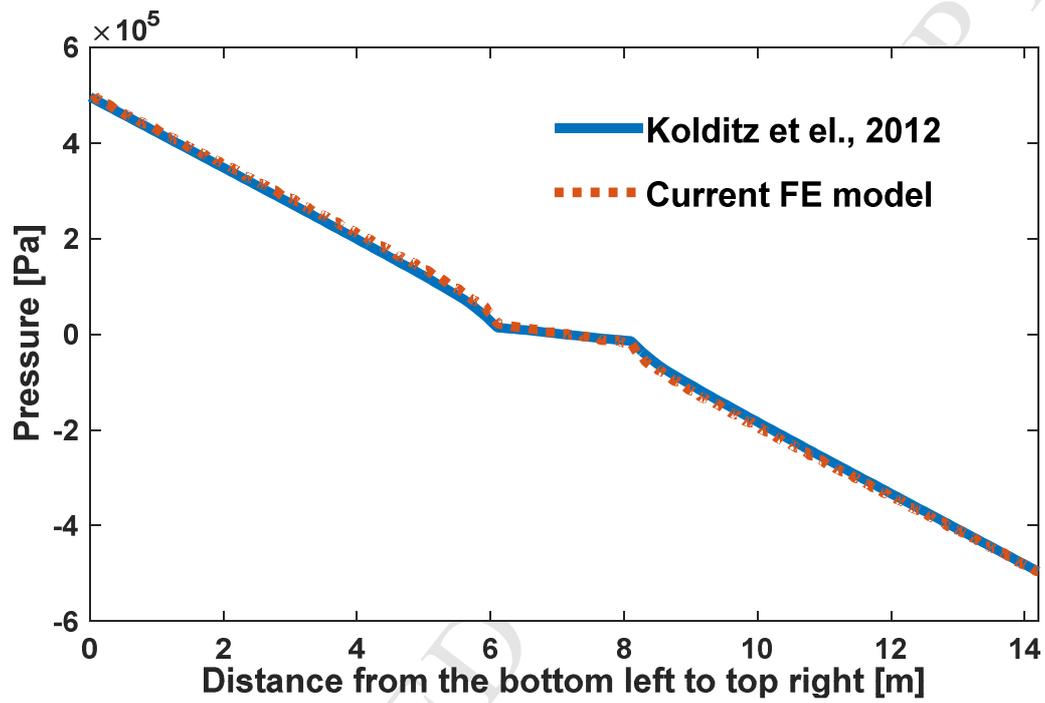

Figure 4: Pressure profile along a diagonal line from the bottom-left passing via the fracture to the top-right
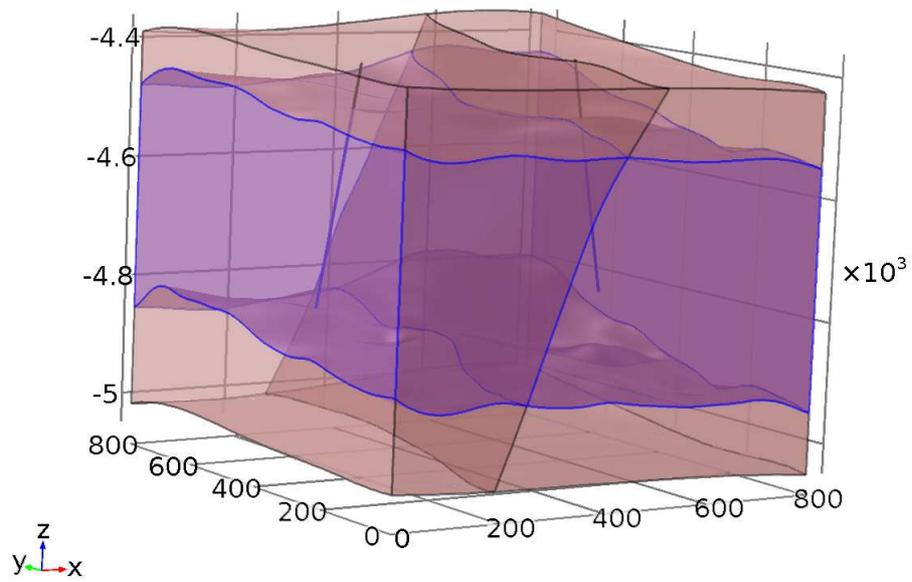

Figure 5(a): Reservoir geometry
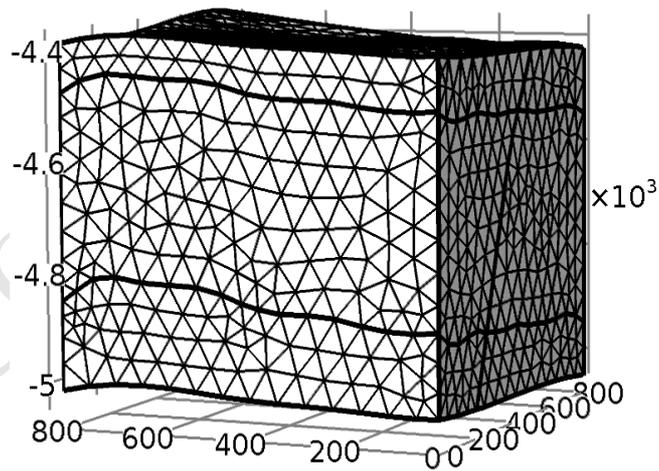

Figure 5(b): Reservoir mesh
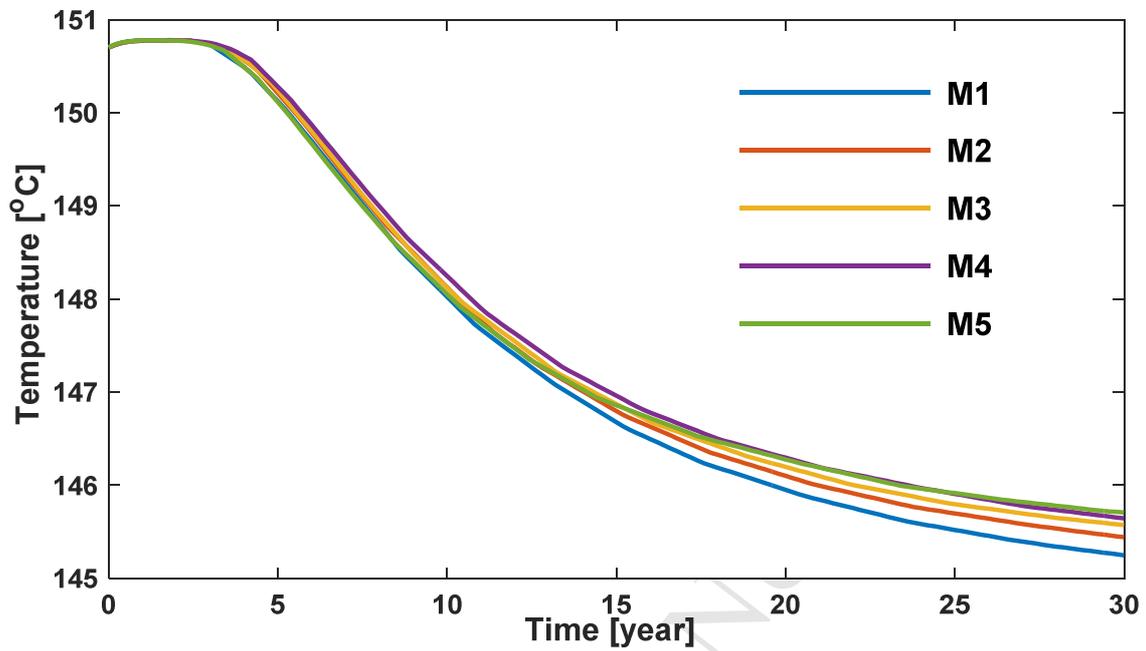

Figure 5(c): Mesh convergence study
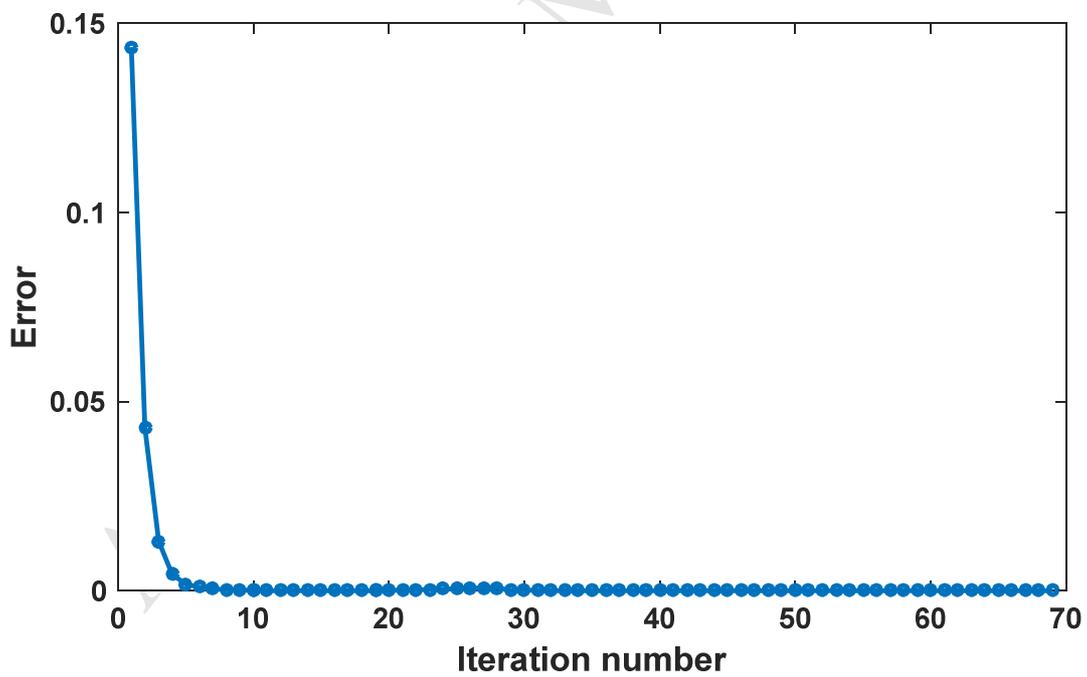

Figure 5(d): Error estimation

Figure 5: Case study of the geothermal reservoir model, mesh with the solution convergence
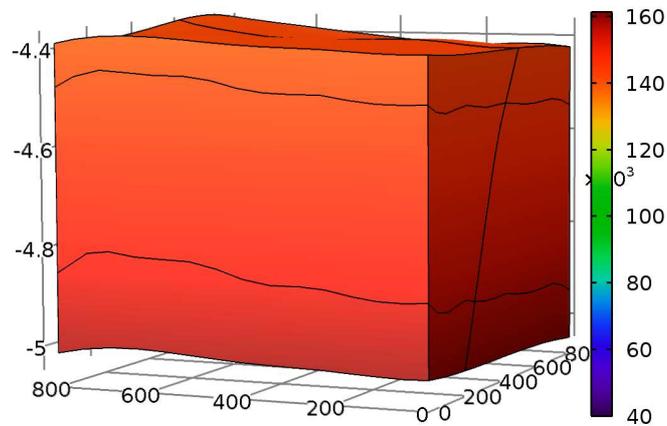

(a) At 0 year
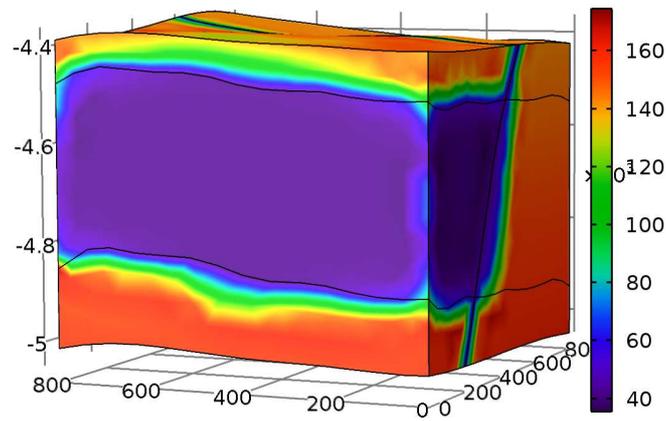

(b) After 15 year
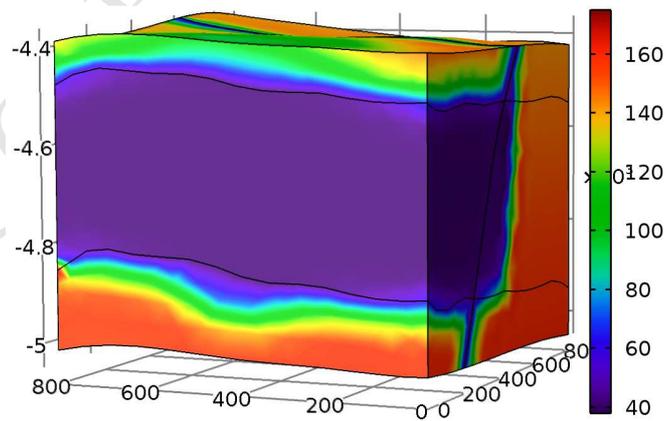

(c) After 30 year

Figure 6: Matrix cold water front distribution (°C) at different stages of simulations

(a) 600 m well spacing at 1 year

(b) 700 m well spacing at 1 year

(c) 600 m well spacing at 15 years

(d) 700 m well spacing at 15 years

(e) 600 m well spacing at 30 years

(f) 700 m well spacing at 30 years
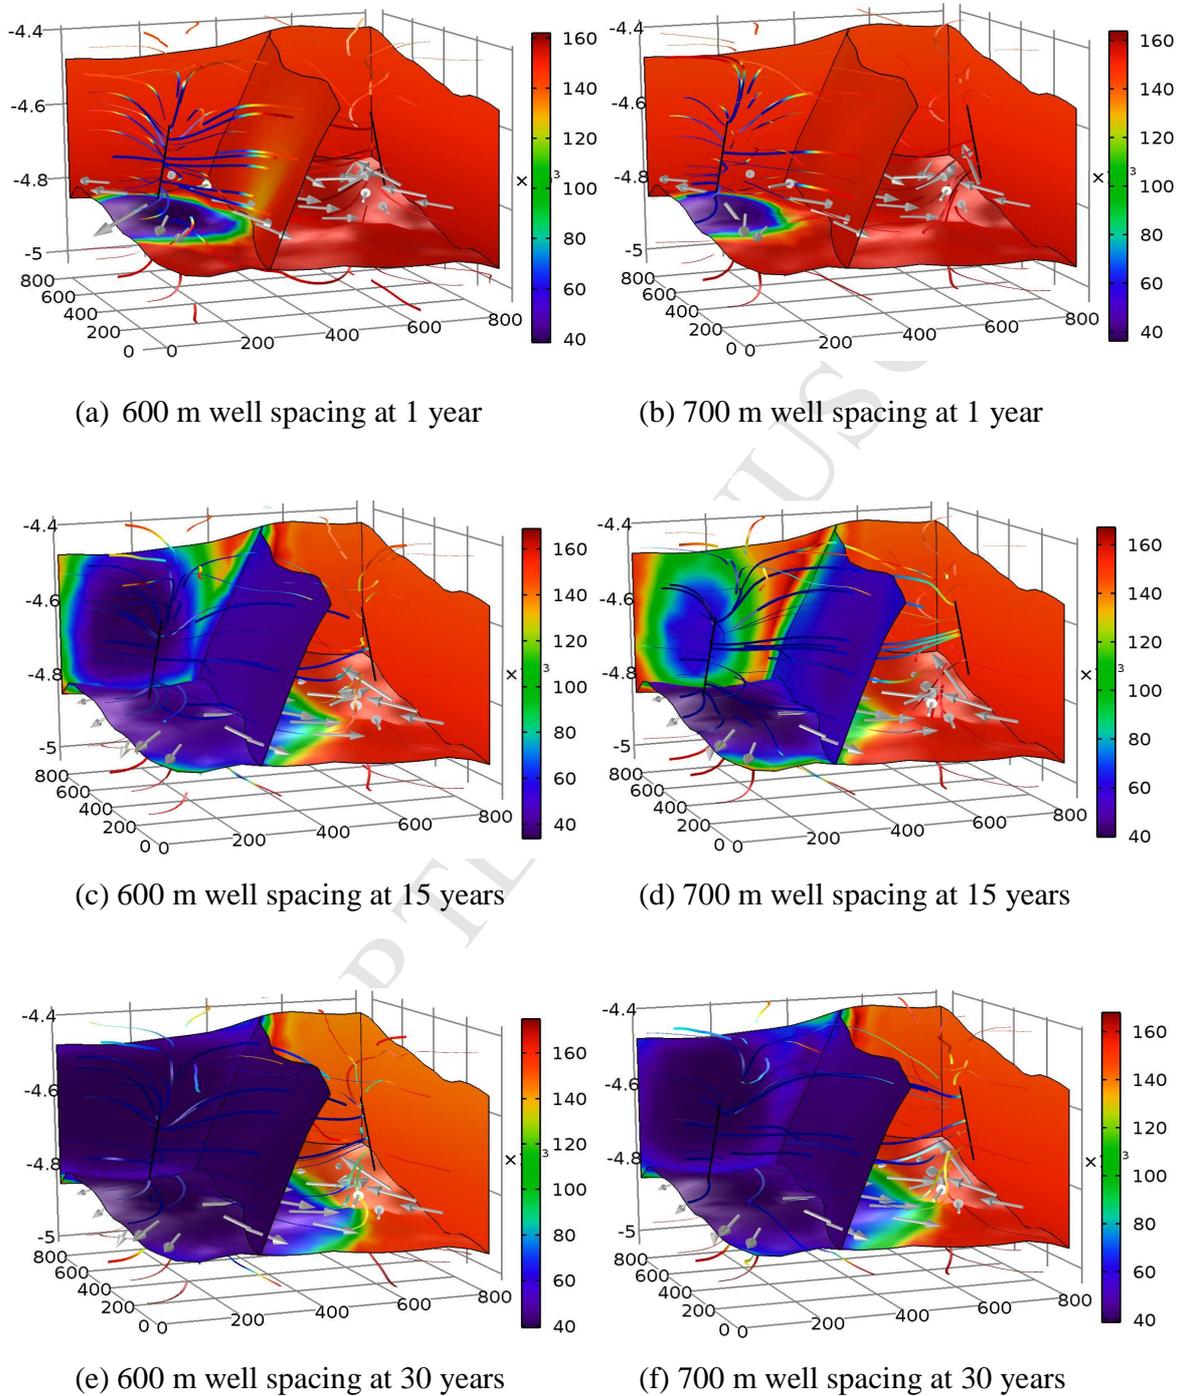

Figure 7: Cold water front propagation within the reservoir (°C) for different well spacing at various stages of simulations
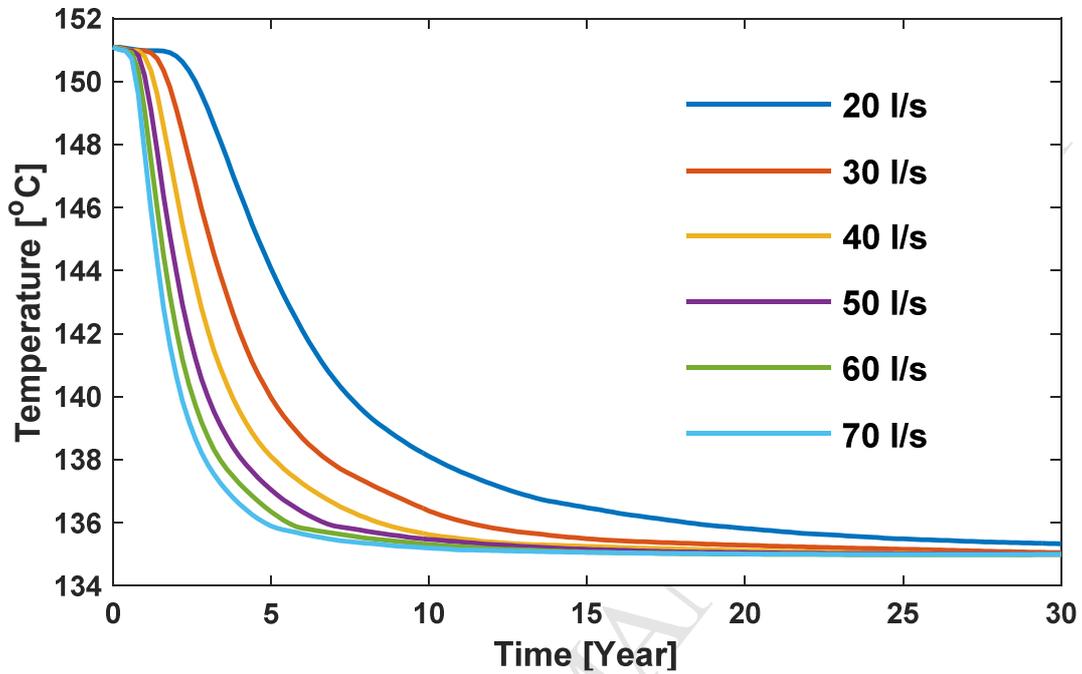

(a) Fluid injection temperature 40°C with 600 m lateral well spacing
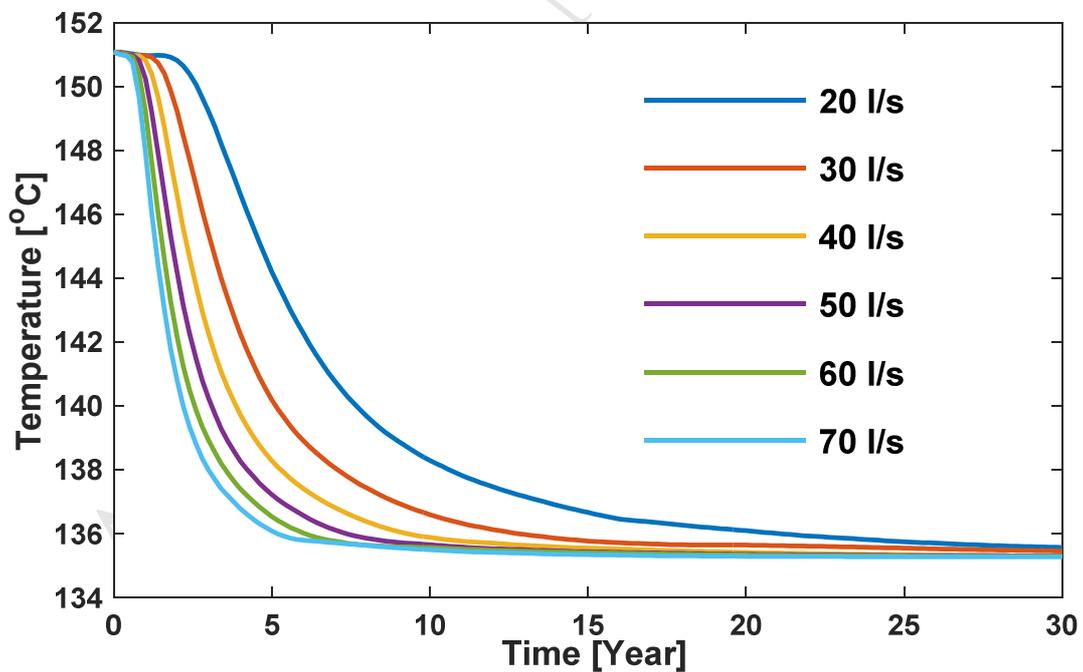

(b) Fluid injection temperature 50°C with 600 m lateral well spacing
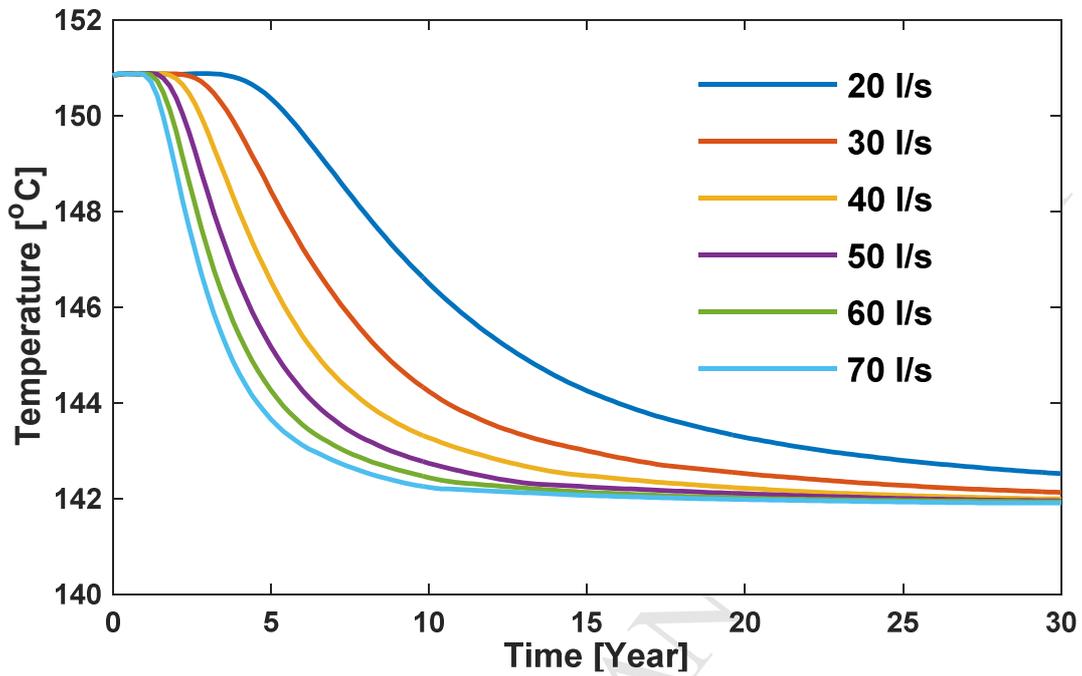

(c) Fluid injection temperature 40°C with 700 m lateral well spacing
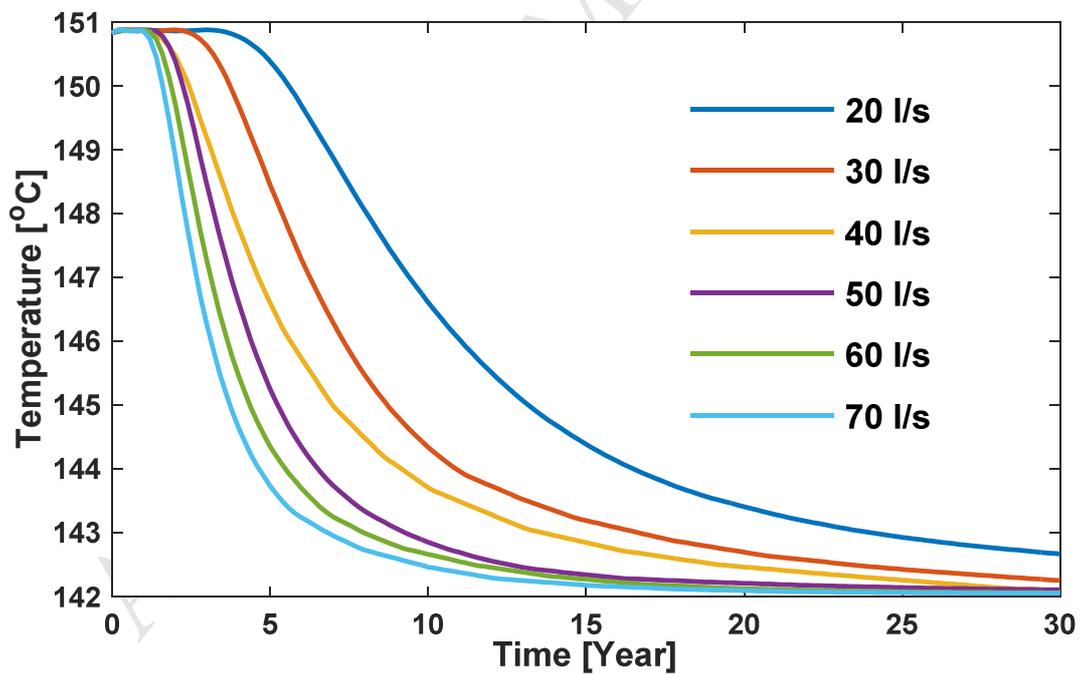

(d) Fluid injection temperature 50°C with 700 m lateral well spacing

Figure 8: Production wellhead temperature under the effect of various injection flow rate ranging from 20 to 70 l/s
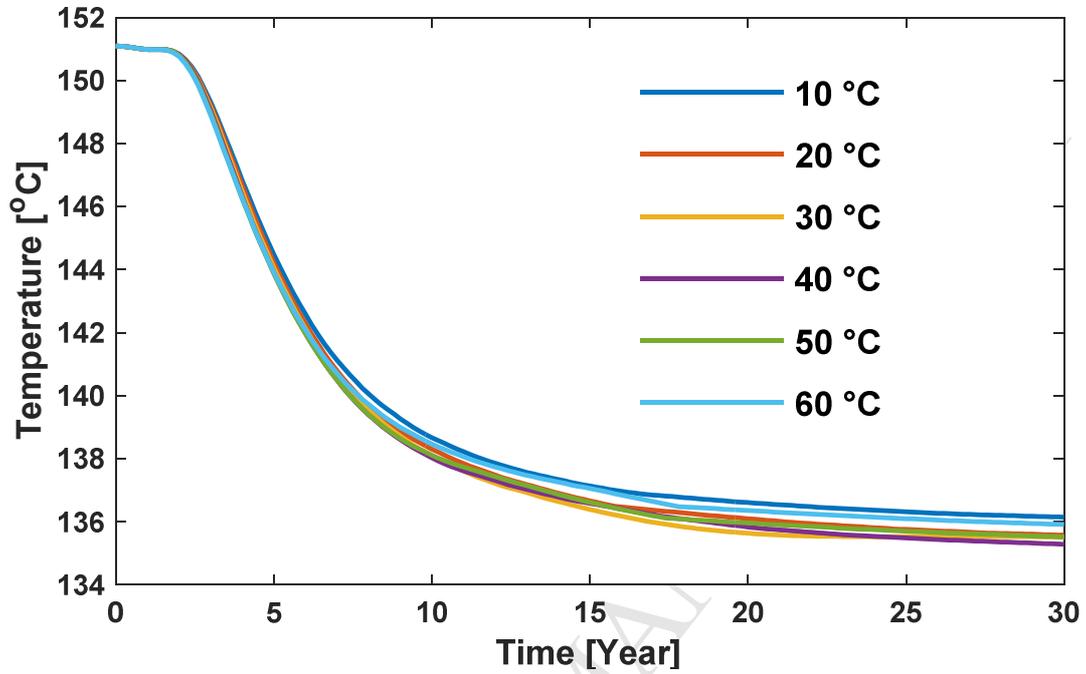

(a) Fluid injection rate 20 l/s with 600 m lateral well spacing
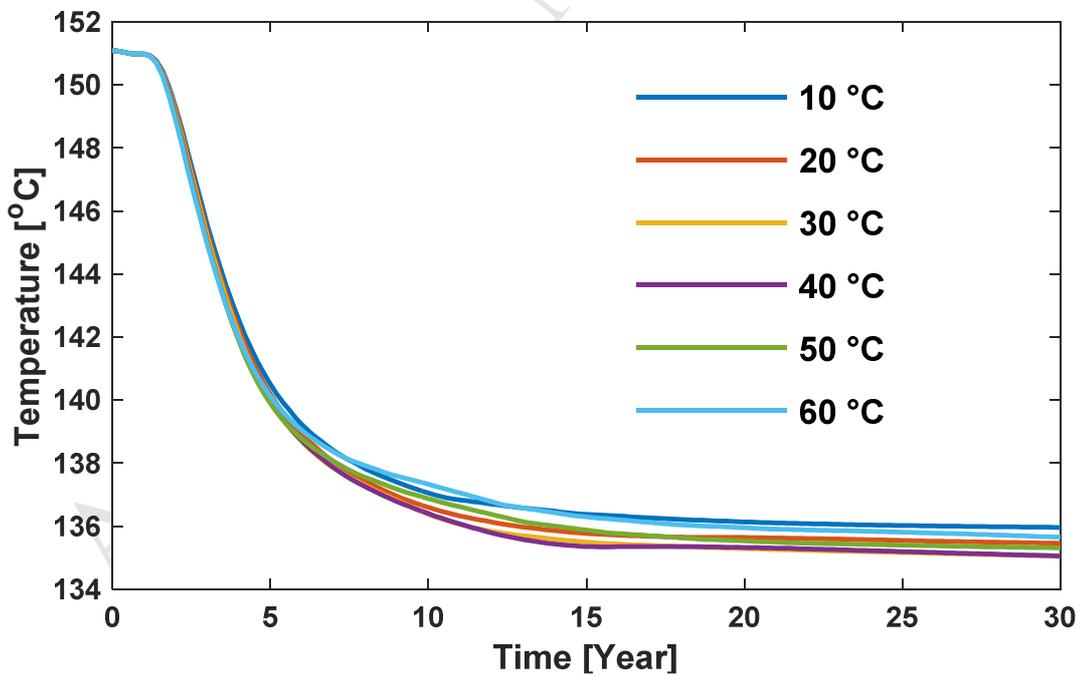

(b) Fluid injection rate 30 l/s with 600 m lateral well spacing
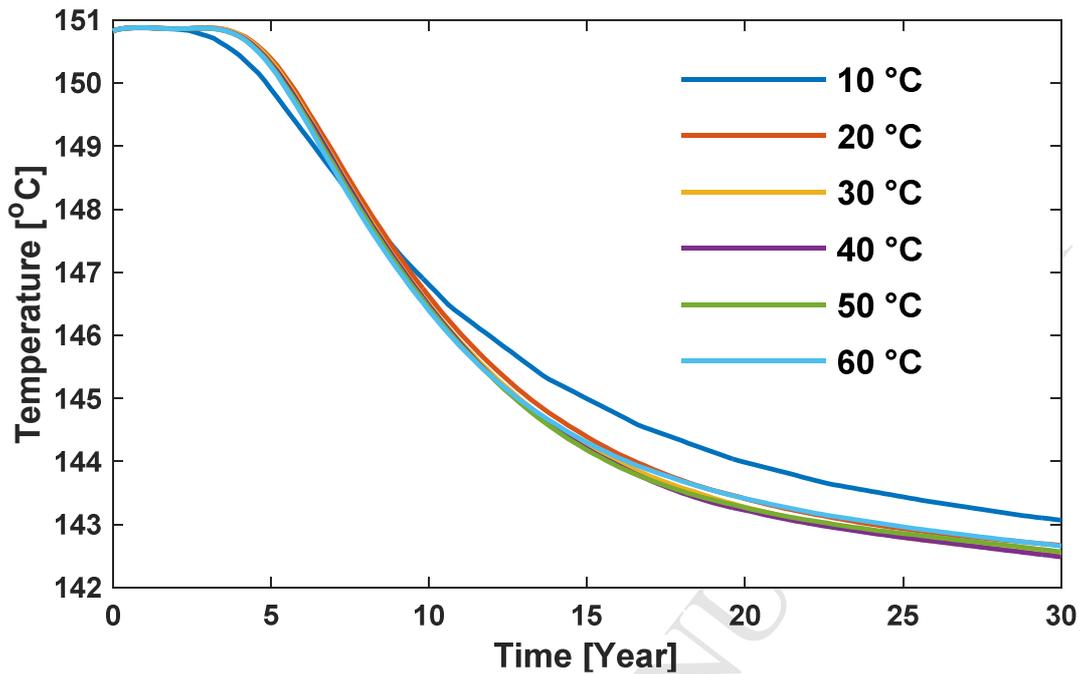

(c) Fluid injection rate 20 l/s with 700 m lateral well spacing
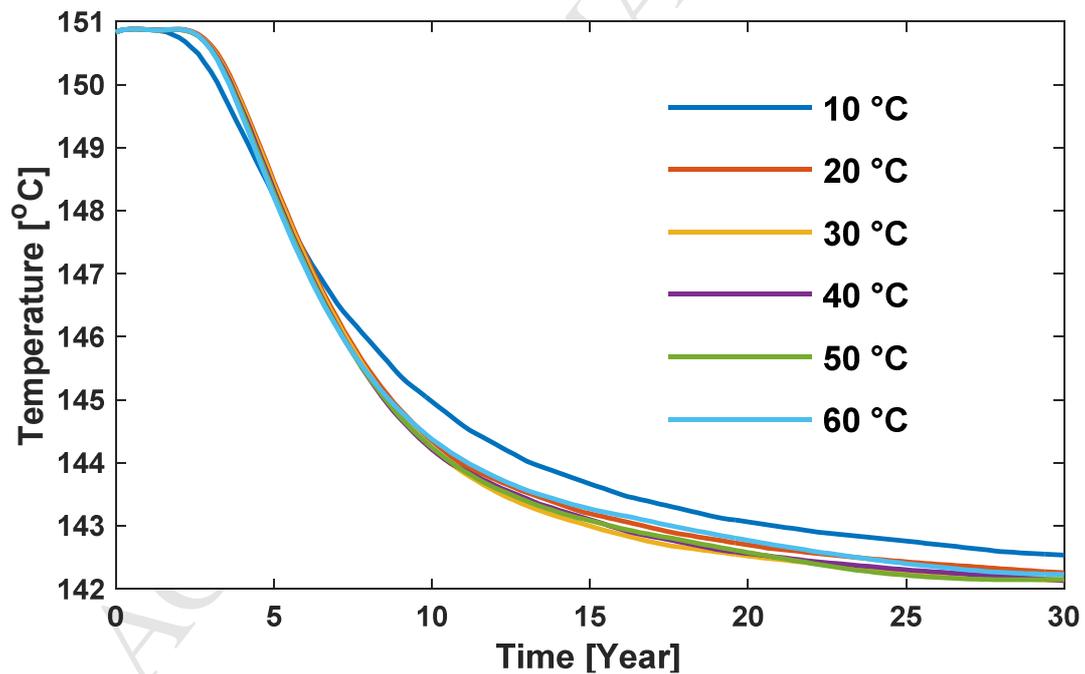

(d) Fluid injection rate 30 l/s with 700 m lateral well spacing

Figure 9: Production temperature over time due to the effect of various injection fluid temperatures ranging from 10°C to 60°C
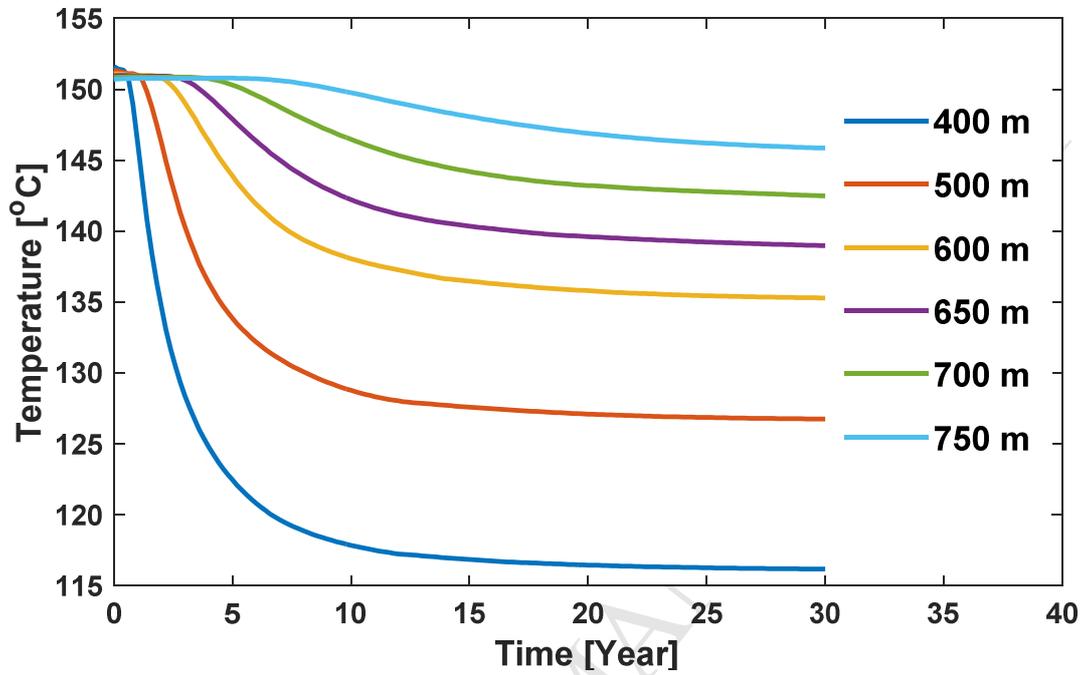

(a) Fluid injection rate 20 l/s with 30°C injection fluid temperature
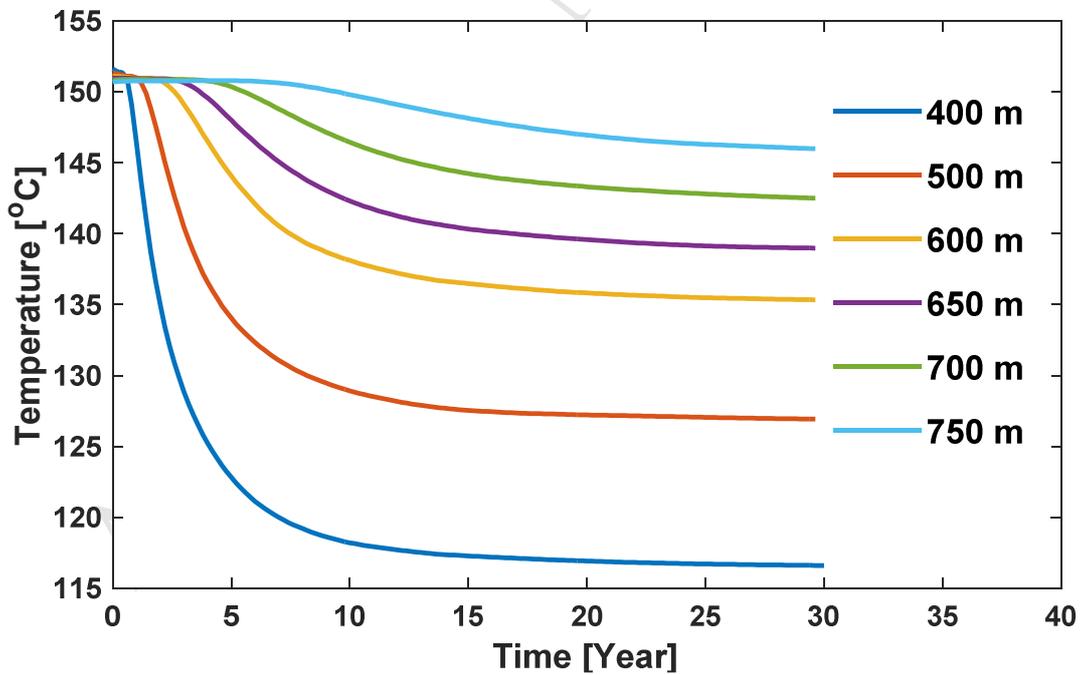

(b) Fluid injection rate 20 l/s with 40°C injection fluid temperature
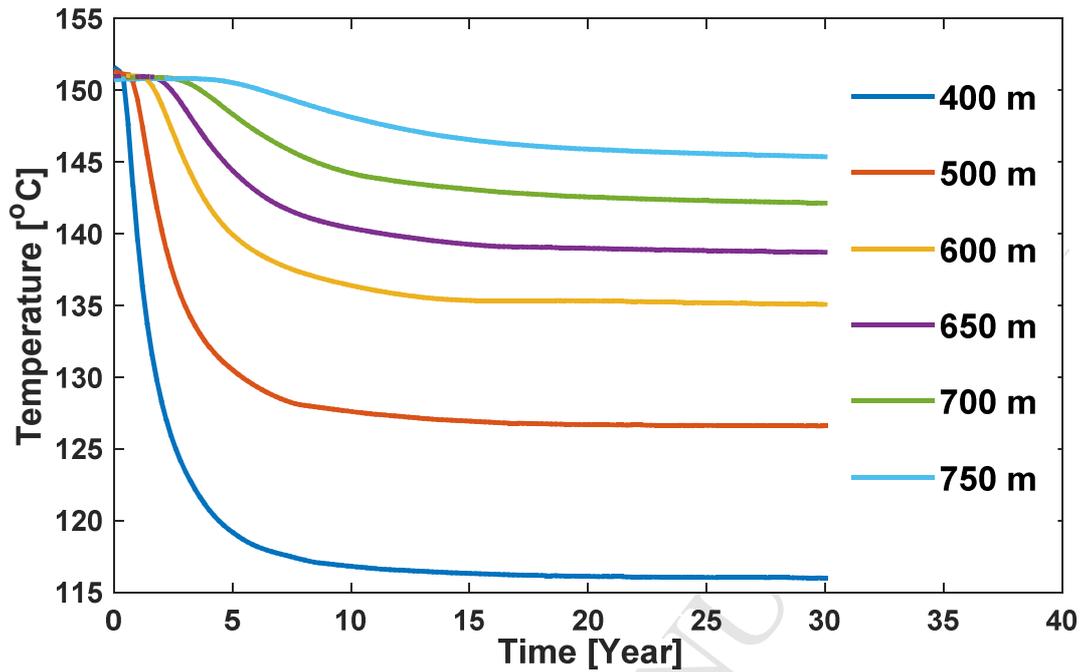

(c) Fluid injection rate 30 l/s with 30°C injection fluid temperature
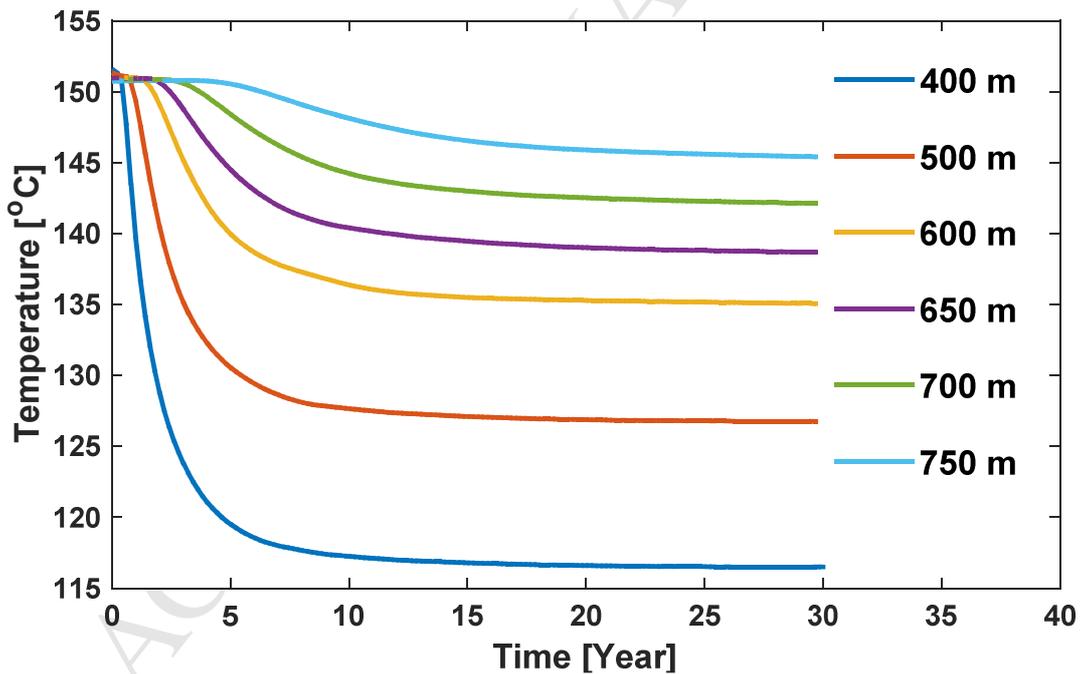

(d) Fluid injection rate 30 l/s with 40°C injection fluid temperature

**Figure 10**: Production temperature over time due to the effect of various lateral well spacing
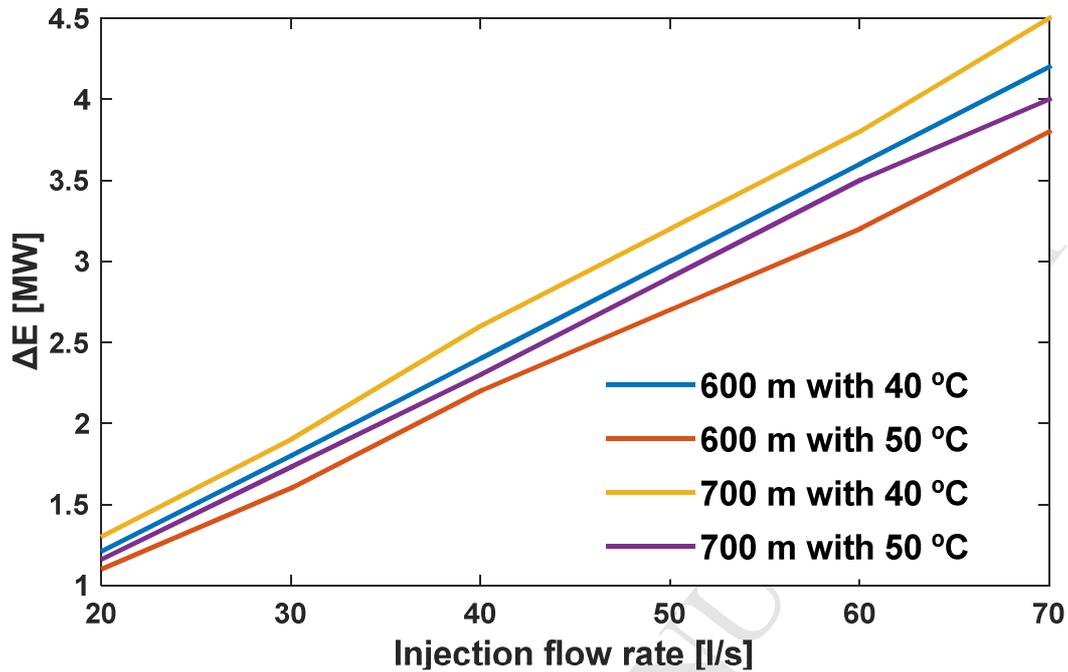

Figure 11: Production energy as function of fluid injection rate under different lateral well spacing and fluid injection temperatures

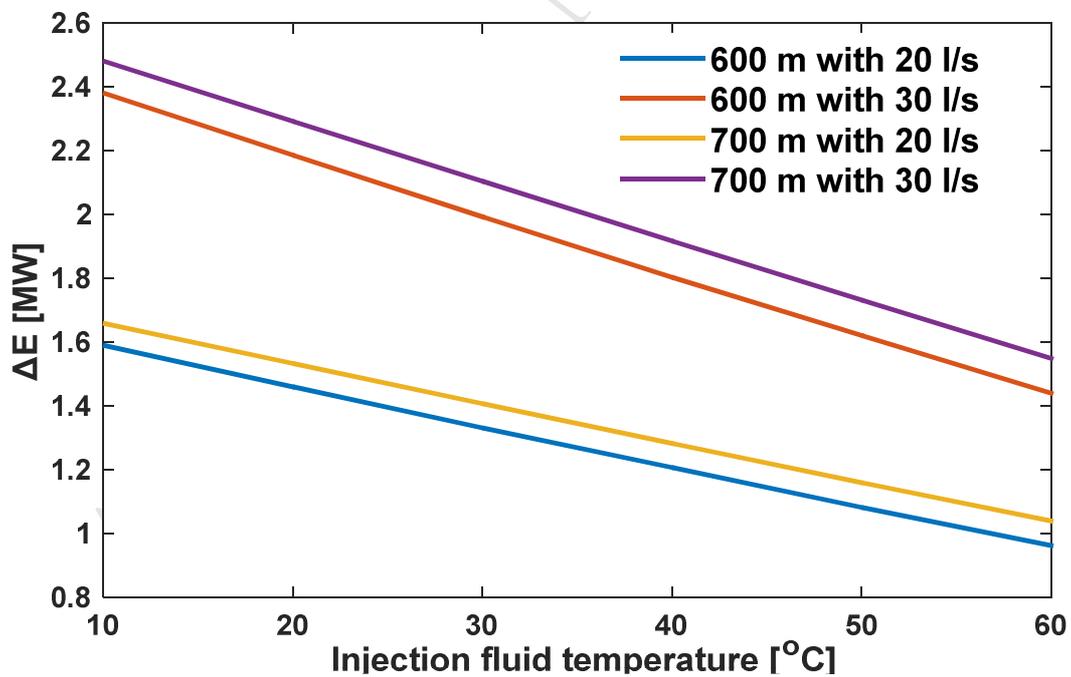

Figure 12: Production energy as function of fluid injection temperature under different lateral well spacing and fluid injection rates
