## ABSTRACT

The syndrome called depression may represent the common final pathway at which different aetiopathogenic processes converge. One such aetiopathogenic process is innate immune system activation. Some depressed patients have increased levels of inflammatory cytokines and other immunologic abnormalities. It is not known whether immune system activation contributes to the pathogenesis of depressive symptoms. Supporting this possibility is the observation that in both rodents and humans, exogenous immune stimuli such as endotoxin can produce symptoms that resemble depression. A new approach to depression research would be to use immune stimuli to elicit depressive symptoms in humans. Here we review each of the symptoms elicited in humans by endotoxin administration, and compare this model to two other immune depression paradigms: interferon-alpha treatment and typhoid vaccine administration, to assess to what degree endotoxin administration represents a valid model of immune depression. We also review corresponding behavioral changes in rodents and the potential molecular pathways through which immune system activation produces each symptom.

## 1. Depression and inflammation

### 1.1. Depression

Major Depressive Disorder (“depression”) is a highly prevalent and severely debilitating disorder for which current treatments are inadequate and the pathogenesis of which is poorly understood. Depression is a syndrome that affects various symptom domains (Kennedy, 2008), and its diagnosis requires the presence of five or more of the symptoms listed in Table 1 (APA, 2000). Although its causes are unknown, the current conceptualization of depression posits that it occurs as a combination of certain biological vulnerability factors and exposure to life-stressors such as trauma or loss (Krishnan and Nestler, 2008). One out of six persons will experience at least one episode of depression in their life (Kessler et al., 2005), and in many individuals depression becomes a chronic, disabling illness (Murray and Lopez, 1997). In addition to significant disability, depression is associated with excess mortality (Zheng et al., 1997; Cuijpers and Smit, 2002), mostly because of co-morbidity with cardiovascular disease, diabetes and obesity. As the pathophysiology of depression has not been fully elucidated, treatments are based on empirical data, not mechanisms of action. Current antidepressants, all of which target monoamines (serotonin, norepinephrine, or dopamine), ameliorate symptoms in about half of patients (Trivedi et al., 2006) and produce remission in only a third (Rush et al., 2006). It remains unclear how these drugs actually work, since their ability to increase synaptic concentrations of monoamines is immediate, while their clinical effects take 2–4 weeks to become apparent (Taylor et al., 2006). Although it is plausible that subtle differences in neurotransmitter profiles could explain differences in efficacy (Millan, 2006), differences in efficacy, which are very small and detectable only in large clinical samples, do not correspond to any known combinations of receptor and reuptake effects (Cipriani et al., 2009). This highlights our lack of understanding of the pathophysiology of depression.

**Table 1**  
Areas of impairment in depression and corresponding diagnostic criteria.

Area of impairment	DSM-IV diagnostic criterion
Mood	Depressed mood
Motivation	Markedly diminished interest or pleasure
Food	Weight loss or gain or decrease or increase in appetite
Sleep	Insomnia or hypersomnia
Motor	Psychomotor retardation or agitation
Energy	Fatigue or loss of energy
Self-esteem	Feelings of worthlessness or excessive or inappropriate guilt
Cognition	Diminished ability to think or concentrate, or indecisiveness
Hope	Recurrent thoughts of death, recurrent suicidal ideation

### 1.2. Depression and inflammatory cytokines

One area of research that may shed light on the pathogenesis of depression is brain–immune interactions. Immunologic abnormalities in depression have been described for over two decades (Irwin and Miller, 2007; Miller et al., 2009), but it is still unclear whether these abnormalities play a role in depression pathogenesis. For readers not familiar with immunology, in Table 2 we describe the main functions of cytokines discussed in this article. The most consistent finding is that patients with depression have elevated levels of inflammatory markers in plasma or serum (Hamer et al., 2009; Howren et al., 2009). Summarized in Tables 3 and 4 are some of the studies that have found elevated levels of the inflammatory cytokines tumor necrosis factor alpha (TNF) and interleukin-6 (IL-6) in medically healthy patients with depression (Maes et al., 1995; Sluzewska et al., 1995; Zorrilla et al., 2001; Hestad et al., 2003; Penninx et al., 2003; Tuglu et al., 2003; Fitzgerald et al., 2006; Bremner et al., 2007; O'Brien et al., 2007; Sutcgil et al., 2007; Yang et al., 2007; Himmerich et al., 2008; Dinan et al., 2009; Dome et al., 2009). Depression in the context of

Yang et al. (2007)	23 control 33 depressed	9	13	

various “medical” illnesses is also associated with elevated blood levels of inflammatory markers (Elenkov, 2007; Irwin and Miller, 2007; Miller et al., 2008). Although inflammation is believed to play a pathogenic role in many medical illnesses, any causal relationships among medical illness, inflammation and depression remain undetermined. In summary, it has been clearly established that both idiopathic depression in medically healthy individuals and depression that occurs in the context of various medical illnesses, are associated with elevated blood levels of inflammatory mediators.

### 1.3. Antidepressant and anti-inflammatory agents

Although some studies found elevated inflammatory cytokine levels in remitted depressed patients (O'Brien et al., 2007; Himmerich et al., 2008), other studies found that inflammatory cytokine levels decreased with various antidepressant treatments (Leonard, 2001; Kenis and Maes, 2002; Hestad et al., 2003; Tuglu et al., 2003; Myint et al., 2005), suggesting that antidepressants may reduce inflammation. This is consistent with anti-inflammatory effects of antidepressants described in rodents (Yirmiya et al.,

2001). Conversely, anti-inflammatory drugs can have an anti-depressant effect. In depressed patients who had not remitted with the antidepressant reboxetine, augmentation with the cyclooxygenase-2 (COX-2) inhibitor celecoxib, which blocks the conversion of arachidonic acid into inflammatory molecules called prostanoids, was superior to placebo (Muller et al., 2006). In patients with psoriasis, the TNF-antagonists infliximab and etanercept reduced depressive symptoms; the latter did so independently of any improvement in joint pain or other psoriatic symptoms (Feldman et al., 2005; Tyring et al., 2006; Bassukas et al., 2008). Such data support the notion that inflammation may in some way contribute to the genesis of depressive symptoms.

### 1.4. Can inflammatory cytokines “cause” depressive symptoms?

It is well-established that inflammatory cytokines released peripherally have profound effects on mood and behavior. Naturally occurring infectious illnesses produce symptoms that resemble depression (Bucks et al., 2008). Experimental studies show that activation of the immune system can cause depressive-like symptoms. In experimental exposure of humans to rhinovirus or influenza virus, blood levels of IL-1, TNF and IL-6 predicted reduced positive affect the following day, independent of objective signs of illness (Janicki-Deverts et al., 2007), and various mild immune stimuli, insufficient to cause significant sickness symptoms, can elicit depressive symptoms in humans (Hermann et al., 1998; Reichenberg et al., 2001; Wright et al., 2005; Capuron et al., 2009; Eisenberger et al., 2009). How does immune activation affect the brain?

## 2. Immune-to-brain and brain-to-immune pathways

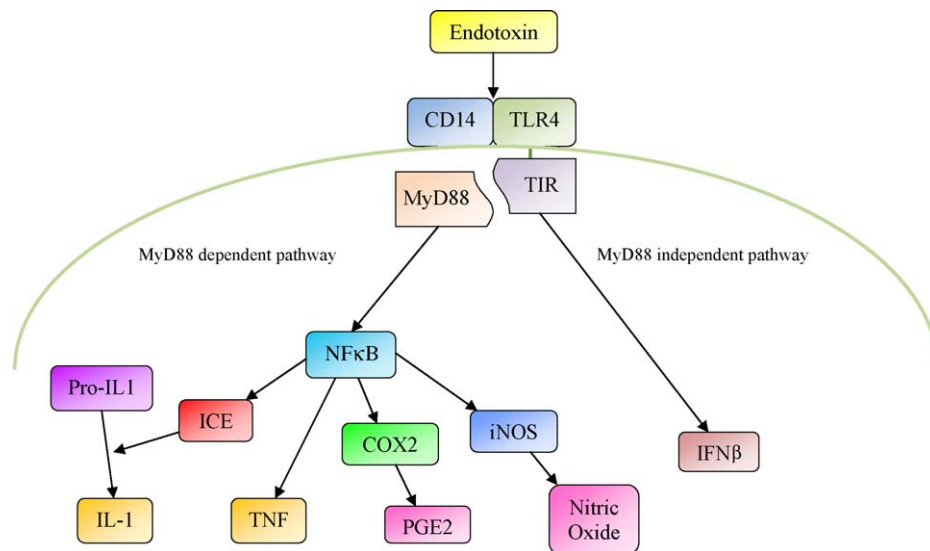

### 2.1. Immune-depression models in rodents

The literature on immune-induced depressive-like behaviors in rodents is vast. Although a comprehensive review of rodent data is not within the scope of this article, we will briefly outline some studies to illustrate how peripheral cytokines “talk” to the brain. For readers interested in this topic, we recommend other reviews (De La Garza, 2005; Dunn et al., 2005; Anisman, 2009; Pecchi et al., 2009). The most commonly used immune-depression model in

**Table 4**

**Fig. 1.** Endotoxin binds to CD14 and Toll-like receptor 4 (TLR4) on the surface of monocytes and endothelial cells. The TLR4 associated Toll-IL-1-receptor domain (TIR) binds to myeloid differentiation factor 88 (MyD88), which, through various intermediate steps, leads to the activation of nuclear factor  $\kappa$ B (NF $\kappa$ B). This transcription factor initiates the transcription of various inflammatory mediators, including tumor necrosis factor (TNF), interleukin-1 converting enzyme (ICE) which converts pro-IL-1 into bioactive IL-1, cyclooxygenase-2 (COX-2) which converts arachidonic acid into prostanooids such as prostaglandin E2 (PGE2), and inducible nitric oxide synthase (iNOS) which produces nitric oxide. The MyD88-dependent pathway can also be activated by IL-1 and TNF signaling through their cognate receptors. The MyD88-independent pathway leads to the transcription of interferon- $\beta$  (IFN- $\beta$ ).

rodents is intraperitoneal (i.p.) administration of endotoxin, a component of the wall of Gram-negative bacteria. Activation of the innate immune system with endotoxin leads to a constellation of behaviors similar to depression in humans: anhedonia, decreases in novelty-induced and social behaviors, reduced food intake, and sleep disturbance (Larson and Dunn, 2001). The production of so-called sickness behavior in rodents occurs when peripherally released cytokines induce expression of inflammatory mediators in brain parenchyma (Pecchi et al., 2009). This has also been demonstrated in primates: cerebrospinal fluid (CSF) levels of IL-6 increase after i.v. administration of IL-1 in monkeys (Reyes and Coe, 1996) and after IFN- $\alpha$  treatment in humans (Raison et al., 2008). It is therefore reasonable to assume that immune-to-brain pathways are similar in rodents and humans. Depending on the dose of endotoxin used, depressive-like behaviors in rodents may continue after the acute sickness behavior ends (Frenois et al., 2007). Such delayed effects from immune stimuli may occur because increased brain and peripheral levels of cytokines can last for several weeks (Qin et al., 2007; Moreau et al., 2008).

## 2.2. Immune-to-brain pathways

What are the pathways through which endotoxin, when administered peripherally, can cause depressive-like behaviors? Innate immune cells have receptors that recognize endotoxin and other so-called pathogen-associated molecular patterns. As illustrated in Fig. 1, endotoxin binds to CD14 which enables interaction with Toll-like receptor 4 (TLR4). This ultimately leads to the activation of the transcription factor NF $\kappa$ B and expression of various genes, including COX-2, TNF, IL-6, IL-1 converting enzyme (ICE) which cleaves pro-IL-1 into bioactive IL-1, and inducible nitric oxide (iNOS) which produces nitric oxide (Gaestel et al., 2009). The NF $\kappa$ B pathway is also activated when IL-1 or TNF bind to their respective receptors. In addition to leukocytes, the NF $\kappa$ B pathway is functional in endothelial cells where it can be activated by endotoxin binding to TLR4/CD14 as well as through TNF and IL-1 binding to their receptors (Dauphinee and Karsan, 2006; Magder et al., 2006). The endothelium and the blood–brain barrier play an

essential role in mediating inflammatory signals from both the bloodstream and cerebral ventricles to brain parenchyma: the myeloid differentiation factor 88 (MyD88) is required in endothelial cells to mediate the effects of peripherally administered IL-1 on the brain (Gosselin and Rivest, 2008), and when IL-1 is administered intracerebroventricularly (i.c.v.), the presence of IL-1 receptors on endothelial cells is necessary for activation of hypothalamic neurons and the occurrence of sickness behavior (Ching et al., 2007). In addition to the endothelium and blood–brain barrier, the brain can also detect peripheral inflammatory signals through afferent vagal fibers (Kapas et al., 1998; Opp and Toth, 1998). Thus, when IL-1 was given i.v., activation of hypothalamic neurons and the occurrence of depressive-like symptoms required the presence of IL-1 receptors in endothelial cells, whereas when IL-1 was injected i.p., endothelial IL-1 receptors were not required (Konsman et al., 2000). Recently, an additional pathway of immune-to-brain communication has been demonstrated, namely the entry of peripheral monocytes into brain parenchyma (D'Mello et al., 2009). In mice with hepatic inflammation, monocytes from the blood enter brain parenchyma, and this process is dependent on TNF-induced expression of monocyte chemoattractant protein-1 in microglia (D'Mello et al., 2009). In summary, peripheral immune stimuli can affect the brain through various pathways, including signaling across the blood–brain barrier, through vagal afferents, and by direct entry of peripheral leukocytes into brain parenchyma (Fig. 2).

## 2.3. Brain-to-immune pathways

Not only can the immune system affect the brain, the brain also exerts some control over the immune system. One of the most important anti-inflammatory mechanisms is the hypothalamic–pituitary–adrenal (HPA) axis. Activation of the HPA axis by peripherally released inflammatory cytokines leads to secretion of cortisol, which has potent anti-inflammatory effects (Bierhaus et al., 2003). In addition, the vagus also exerts anti-inflammatory effects through the release of acetylcholine which acts directly on nicotinic receptors on immune cells (Pavlov and Tracey, 2005).

**Table 5**

Endotoxin-induced TNF and IL-6 plasma levels.

they occur in the context of idiopathic depression or as a consequence of an inflammatory stimulus, may involve overlapping neural pathways. Because of this, the study of depressive symptoms induced by immune stimuli may deepen our understanding of this serious disorder. To do this we need validated human models of immune depression.

### 3. Human models of immune depression

#### 3.1. The interferon-alpha model

In patients with hepatitis C treated with interferon-alpha (IFN- $\alpha$ ) up to 45% develop depression (Asnis and De La Garza, 2006). The symptoms that occur after IFN- $\alpha$  treatment resemble idiopathic depression (Capuron et al., 2009) and respond to treatment with antidepressants (Musselman et al., 2001; Kraus et al., 2007), lending both face and predictive validity to this model. Of note, IFN- $\alpha$ -induced depressive symptoms are associated with increases in blood levels of IL-6 and TNF akin to levels found in depression (Taylor and Grossberg, 1998; Wichers et al., 2007), suggesting that the depressogenic effect of IFN- $\alpha$  is mediated by inflammatory cytokines. Studies using the IFN- $\alpha$  model have greatly expanded our knowledge of the role of inflammation in depression, and this model of chronic, low-grade inflammation may mimic the effects of peripheral inflammation on the brain that occur in idiopathic depression. One limitation of this model is that, because the depressogenic effects of IFN- $\alpha$  do not usually occur until 8–12 weeks of treatment (Asnis and De La Garza, 2006), it cannot be used as an acute laboratory paradigm of immune depression. Furthermore, the IFN- $\alpha$  model is not double-blind and cannot be applied to healthy volunteers. Therefore it would greatly benefit the field of

depression research to develop complimentary models of immune depression.

#### 3.2. The typhoid vaccination model

Administration of the typhoid vaccine is a mild immune stimulus that acutely induces subtle changes in mood (Strike et al., 2004), and slight increases in IL-6 blood levels see Table 5, without any effect on TNF (Wright et al., 2005). This model also induces fatigue and impairs concentration (Harrison et al., 2009a,b).

#### 3.3. The endotoxin model

As described in Section 2.2, endotoxin is a component of the outer membrane of Gram-negative bacteria that, when administered to rodents or humans, leads to activation of the innate immune system. Endotoxin administration in human subjects is a generally safe experimental procedure that has been used for several decades to study the systemic response to innate immune system activation (Lowry, 2005). In humans, endotoxin doses of 2–4 ng/kg body weight cause flu-like symptoms (fever, chills, myalgia, headache, nausea) and increases in blood TNF and IL-6 levels similar to what is seen in sepsis (Michie et al., 1988; van der Poll et al., 1997; van Eijk et al., 2007), while lower doses (0.4–0.8 ng/kg) cause mild depressive symptoms and less pronounced increases in TNF and IL-6 levels (Reichenberg et al., 2001; Vedder et al., 2007; Eisenberger et al., 2009). The inflammatory cytokine blood levels achieved at different doses of endotoxin are summarized in Table 5. Although there is a clear dose–response relationship between the potency of the endotoxic stimulus and blood levels of TNF and IL-6, there are large individual differences

in the immune response, rendering the use of endotoxin to experimentally induce depressive symptoms challenging. The purpose of this paper is to review whether endotoxin administration can be used as a model of acute immune depression. We will review the effects of the IFN- $\alpha$  and typhoid vaccination models in parallel as a side-by-side comparison of the three models. Rather than approach depression as a categorical construct, we will review the effect of these immune stimuli on each of the symptoms that constitute the syndrome called depression. We will also include select rodent studies that highlight the potential pathways through which peripherally released cytokines produce the rodent-equivalent of each of the symptoms discussed.

#### 4. Depressed mood

Depressed mood is one of two core symptoms of depression (Kennedy, 2008), and one study showed that acute infection is associated with reduced “contentment” (Bucks et al., 2008). Two studies concluded that low-dose endotoxin administration (0.8 ng/kg) induced depressed mood (Reichenberg et al., 2001; Eisenberger et al., 2009). In the first study ( $n = 20$ , cross-over), the Depression Adjective Check List (DACL) (Christenfeld et al., 1978) showed a statistically significant difference in depressed mood at 3 h after endotoxin administration compared to the placebo condition, and DACL scores correlated with TNF plasma levels (Reichenberg et al., 2001). The DACL has been shown to correlate well with the Beck Depression Inventory (BDI) and other more commonly used depression rating scales (Christenfeld et al., 1978).

In the second study ( $n = 39$ , parallel-group) depression was measured with the Profile of Mood States (POMS), and there was a statistically significant difference in the POMS Depression-Dejection subscale (POMS-D) score between the endotoxin and placebo groups, but no correlation between POMS-D scores and IL-6 plasma levels (Eisenberger et al., 2009). POMS assesses six identified mood factors: Tension-Anxiety, Depression-Dejection, Anger-Hostility, Vigor-Activity, Fatigue-Inertia, and Confusion-Bewilderment, however, only Anger-Hostility, Vigor-Activity, and Fatigue-Inertia have considerable factorial integrity (Norcross et al., 1984). Therefore it is not clear that the POMS-D is a reliable measure of depression or depressed mood. Moreover, since the maximum score on the POMS-D subscale is 20, the clinical relevance of a mean score of 0.4 is debatable. Consistent with (Eisenberger et al., 2009), in eight healthy subjects who received low-dose endotoxin (0.8 ng/kg) in a placebo-controlled, cross-over study, the mean POMS-D score after endotoxin was 0.3 compared to 0 after placebo (Hannestad unpublished). Moreover, the “Reported Sadness” item of the Montgomery-Åsberg Depression Rating Scale (MADRS) did not change in any subject, nor did BDI items 1 (feeling sad) or 2 (discouraged about the future) (Hannestad unpublished). It has therefore not been clearly demonstrated that endotoxin administration can cause depressed mood. In the IFN- $\alpha$  model, “Depressed Mood” on the Hamilton Depression Rating Scale increased in both IFN- $\alpha$ -related depression and idiopathic depression (Capuron et al., 2009), while the typhoid vaccine model has only been evaluated using the POMS (Strike et al., 2004). Using the typhoid vaccination model during functional magnetic resonance imaging, it was demonstrated that inflammation-associated mood deterioration correlated with enhanced activity in the subgenual anterior cingulate cortex (Harrison et al., 2009a,b). In summary, more research is needed to assess whether endotoxin administration in humans can induce depressed mood. As rodent studies of depressed mood cannot be performed, we have no data indicating the immune-to-brain pathways that mediate the effects of peripheral inflammation on mood.

#### 5. Anhedonia

##### 5.1. Immune-induced anhedonia in humans

Anhedonia, the lack of ability to experience pleasure or reward, is the other core symptom of depression (Kennedy, 2008). Although anecdotally one could assume that interest would be reduced during acute infections, there are no published studies that have empirically tested this idea. There are also no published studies assessing the effect of endotoxin on anhedonia in humans. In our cohort we found no change in the “Inability to feel” item on the MADRS, however, we did find that when subjects were asked on a visual-analog scale whether they “Want to be alone” or “Want to be with other people”, endotoxin administration reduced the desire for social interactions (Hannestad unpublished). This is consistent with rodent studies (see below). Although not an official DSM-IV diagnostic criterion, one very common symptom in depression is reduced libido (Williams and Reynolds, 2006). Reduced libido can be construed as a type of anhedonia, however, there are no data on the effect of endotoxin on libido in humans. Compared to the endotoxin model, in patients who received IFN- $\alpha$  treatment, the Hamilton Depression Rating Scale item “Work/Activities” was similar in IFN- $\alpha$  and idiopathic depression (Capuron et al., 2009) indicating that the IFN- $\alpha$  model does induce anhedonia. There are no published data on the effect of typhoid vaccination on anhedonia. In summary, there is insufficient data to assess whether endotoxin administration in humans is a useful model of anhedonia.

##### 5.2. Immune-induced anhedonia in rodents: sucrose preference

The literature on endotoxin-induced anhedonia in rodents is extensive (Anisman and Matheson, 2005; De La Garza, 2005). One rodent model of anhedonia is sucrose preference, i.e. increased preference for palatable foods such as sugared water. Sucrose preference is inhibited by endotoxin, IL-1 and TNF (Brebner et al., 2000; De La Garza et al., 2005a,b; Weil et al., 2006), while the data regarding the effects of IFN- $\alpha$  are inconclusive (Sammur et al., 2001; De La Garza et al., 2005a,b; Loftis et al., 2006a,b; Fahey et al., 2007). The inconsistent findings with IFN- $\alpha$  in rodents may be because earlier studies used human recombinant IFN- $\alpha$  which does not induce signal transduction in rodent receptors (Loftis et al., 2006a,b). On the other hand, IFN- $\gamma$ , when over-expressed in the central nervous system, did reduce sucrose preference (Kwant and Sakic, 2004). Pre-treatment with the antidepressants desipramine and fluoxetine blunts IL-1- and IFN- $\alpha$ -induced reductions in sucrose preference (Sammur et al., 2002; Merali et al., 2003), lending predictive validity to this rodent model of anhedonia. Endotoxin-induced decreases in sucrose preference are blocked by non-steroidal anti-inflammatory agents, whereas endotoxin-induced expression of IL-1 and IL-6 in the hypothalamus is not (De La Garza et al., 2005a,b). This indicates that, while prostanooids are involved in mediating the effect of endotoxin on sucrose preference, hypothalamic expression of IL-1 and IL-6 is not. Although sucrose causes release of dopamine in the nucleus accumbens (de Araujo et al., 2008), the region mediating reward (Pizzagalli et al., 2009), it is likely that sucrose preference is a complex behavior that involves not only brain regions that mediate reward, but also brain regions that control appetite and energy homeostasis such as the hypothalamus and brain stem (Ahima and Antwi, 2008).

##### 5.3. Immune-induced anhedonia in rodents: intracranial self-stimulation

Intracranial self-stimulation (ICSS), a reinforcing electrical stimulation of the forebrain bundle at the level of the posterior

lateral hypothalamus, does not involve appetite regulation and is therefore considered a “purer” rodent model of anhedonia (Liebman, 1983). Endotoxin reduces ICSS and this is associated with increased dopamine efflux and reduced expression of the exocytotic protein syntaxin in the nucleus accumbens (Borowski et al., 1998; Barr et al., 2003). This indicates that peripheral activation of the innate immune system inhibits reward or pleasure. Studies have failed to show an effect of IL-1 and IL-6 on ICSS-anhedonia, although both cause sickness behavior (Anisman et al., 1998) and IL-1 reduces sucrose preference (Brebner et al., 2000), suggesting that (1) the effects of endotoxin on ICSS may involve other cytokines and (2) that ICSS-anhedonia and sucrose preference are mediated by different brain regions. Of note, stimulation of the ventral tegmental area, which supplies dopamine to the nucleus accumbens, counteracted endotoxin-induced sickness behavior (Kentner et al., 2008), further supporting the notion that endotoxin causes anhedonia.

#### 5.4. Immune-induced anhedonia in rodents: exploratory and social behaviors

In rodents, both endotoxin and IL-1 decrease exploration of novel environments and engagement in social behaviors (Larson and Dunn, 2001), lending face validity to the notion that immune stimuli cause anhedonia in rodents. Mice pre-treated with endotoxin had lower neuronal activity in brain regions involved in reward when presented with a new environment (Stone et al., 2006). With regards to sexual behaviors, endotoxin and IL-1 disrupt sexual behaviors only in female rodents with no discernable effects in males (Yirmiya et al., 1995; Larson and Dunn, 2001). In summary, endotoxin administration in rodents produces anhedonia as assessed by sucrose preference, ICSS, and exploratory and social behaviors. The specific cytokines involved have yet to be determined. In humans, there are not enough data to determine whether endotoxin administration is good model of anhedonia. Although this symptom is difficult to measure in a laboratory setting, further studies should be conducted.

## 6. Food intake

### 6.1. Immune-induced suppression of food intake in humans

Lack of appetite, reduced food intake, and weight loss occur frequently in depression, although some patients experience increased appetite (APA, 2000). Similarly, during acute infectious illness appetite is reduced (Langhans, 2007). In humans, low-dose endotoxin reduced food intake in the first 4 h without causing nausea (Reichenberg et al., 2001), and reductions in food intake correlated with plasma levels of TNF and IL-6 (Reichenberg et al., 2002). Treatment with IFN- $\alpha$  also reduces appetite as assessed by the Hamilton Depression Rating Scale, however, this was seen both in patients who developed depressive symptoms and those who did not (Capuron et al., 2009), indicating that IFN- $\alpha$  may reduce appetite independent of other depressive symptoms. There are no published data on the effect of typhoid vaccination on food intake.

### 6.2. Immune-induced suppression of food intake in rodents

The arcuate nucleus, lateral hypothalamus, dorsal vagal complex, and raphe nuclei are the main regions regulating food intake (Dhillon, 2007; Ahima and Antwi, 2008). In rodents, endotoxin and IL-1 induce anorexia (Larson and Dunn, 2001) which involves signaling through the endothelium and the MyD88 pathway (Wisse et al., 2007; Gosselin and Rivest, 2008). Although both endotoxin and IL-1 cause COX-2 expression and prostanoid synthesis in brain endothelium (Dunn et al., 2006; Gosselin and

Rivest, 2008), prostanoid synthesis is only required for IL-1-induced anorexia (Elander et al., 2007; Pecchi et al., 2009), indicating that other mediators are involved with endotoxin. When administered i.c.v., IL-1 only produces anorexia if co-administered with IL-6 (Harden et al., 2008), suggesting that IL-6 signaling in the brain may be required to produce anorexia. Both serotonin and orexin have been implicated in the anorexic effects of endotoxin (Asarian et al., 2007; Langhans, 2007). Although the role of TNF in mediating immune-induced anorexia has been controversial (Larson and Dunn, 2001), TNF deficiency attenuated anorexia induced by staphylococcal enterotoxin A, which in a similar manner to endotoxin induces release of inflammatory cytokines (Rossi-George et al., 2005), indicating that TNF can also produce anorexia. This is consistent with anorexia produced by i.c.v. administration of TNF in pigs (Warren et al., 1997). One potential pathway through which TNF could reduce food intake is by modulating glutamate release in vagal afferents to the solitary tract nucleus and disrupting autonomic control of the gut (Hermann and Rogers, 2007). Supporting the proposed effect of TNF on glutamate receptors are data showing that endotoxin-induced anorexia is inhibited by metabotropic glutamate receptor antagonism (Weiland et al., 2006). In summary, endotoxin administration suppresses food intake in both humans and rodents and may be an adequate experimental paradigm to mimic the loss of appetite and reduced food intake that occurs in idiopathic depression. As we have described above, one caveat is that reduced food intake in depression may involve both brain regions that mediate reward and brain regions involved in food intake and energy regulation.

## 7. Sleep

### 7.1. Immune-induced sleep disturbances in humans

Sleep is almost ubiquitously disturbed in depression. Three out of four patients with depression suffer from insomnia, and among young depressed patients almost half have hypersomnia (Nutt et al., 2008). Sleep is also altered during infections (Imeri and Opp, 2009). Sleep is divided into rapid eye movement (REM) and non-REM sleep. Non-REM is further classified into stages 1 through 4 according to electroencephalographic characteristics, with stages 3 and 4 defined as slow-wave sleep. Upon falling asleep, non-REM sleep is initiated by gamma aminobutyric acid neurons in the ventrolateral preoptic nucleus of the hypothalamus, which inhibit monoaminergic arousal systems located in the locus caeruleus and raphe nuclei. The switch to REM sleep, which occurs after non-REM sleep has initiated, is mediated by cholinergic neurons in the tegmentum of the pons. The sleep abnormalities found in idiopathic depression include disturbances in sleep continuity, reduced slow-wave sleep, shortened REM latency, and increased REM density (Riemann, 2007). In humans endotoxin can disrupt sleep continuity at higher doses (Mullington et al., 2000), however slow-wave sleep is not affected by endotoxin (Trachsel et al., 1994), REM latency is increased rather than shortened (Korth et al., 1996; Hermann et al., 1998), and REM is suppressed (Trachsel et al., 1994). In other words, the effects of endotoxin on sleep are in many regards opposite of what is seen in idiopathic depression (Riemann, 2007). Consistent with this, the direct administration of IL-6 in humans causes decreased REM sleep (Spath-Schwalbe et al., 1998), again opposite of what is seen in idiopathic depression. In patients receiving IFN- $\alpha$  treatment, depression was not associated with significant changes in subjective sleep (Capuron et al., 2009), however there are no published studies of EEG recordings in IFN- $\alpha$ -treated patients. There are no data on the effect of typhoid vaccination on sleep. Interestingly, administration of the TNF antagonist etanercept in abstinent alcoholics

decreased the amount of REM sleep (Irwin et al., 2009). As etanercept does not cross the blood–brain barrier (Griffin, 2008), this suggests that reducing peripheral TNF activity can inhibit REM sleep. This is consistent with rodent studies showing that blocking IL-1 and TNF also interferes with sleep in the absence of infection or immune system activation, pointing to a physiologic role of these cytokines in sleep regulation (Imeri and Opp, 2009). In summary, the effects of endotoxin on sleep do not resemble sleep disturbances found in idiopathic depression.

## 7.2. Immune-induced sleep disturbances in rodents

The effects of endotoxin on sleep are mediated by cytokines (Imeri et al., 2006). Consistent with human studies discussed above, in rodents administration of endotoxin, IL-1, TNF, or IFN- $\gamma$  suppresses REM sleep and enhances the duration of slow-wave sleep (Krueger et al., 1986; Shoham et al., 1987; Krueger and Majde, 1995). Inhibition of ICE abolished enhancement of non-REM sleep by endotoxin (Imeri et al., 2006), and in IL-6 deficient mice endotoxin-induced increases in non-REM sleep were blunted (Morrow and Opp, 2005), demonstrating that both IL-1 and IL-6 are involved in mediating the effects of endotoxin on sleep. TNF receptor antagonism did not abolish the effects of endotoxin on sleep (Lancel et al., 1997), whereas TNF administered i.c.v. in pigs led to hypersomnia (Warren et al., 1997). The effects of peripherally administered endotoxin and IL-1 on sleep are mediated by the vagus (Kapas et al., 1998; Opp and Toth, 1998), and may involve the hypothalamic suppression of genes that regulate circadian rhythm and activity level (Cavadini et al., 2007). Interestingly, chronic infusion of endotoxin into the lateral hypothalamus of rats for 30 days caused increases in wakefulness after 6 days which returned to baseline after endotoxin administration was discontinued (Gerashchenko and Shiromani, 2004). This highlights that the effects of endotoxin on sleep depend on whether administration is acute or chronic. In summary, immune system activation has profound effects on sleep architecture, causing increased non-REM sleep, interruption of REM sleep and increased REM latency, however, these effects on sleep are in many respects the opposite of those seen in depression. Therefore immune system activation with endotoxin is not an adequate model of sleep disturbances seen in depression. Chronic activation of the immune system may be a better model (Gerashchenko and Shiromani, 2004), and the effects of IFN- $\alpha$  on sleep would therefore merit further study.

## 8. Fatigue and psychomotor slowing

### 8.1. Immune-induced fatigue in humans

Fatigue is a prominent symptom in depression (Kennedy, 2008), one that often does not improve with current treatments (Papakostas et al., 2006). Fatigue occurs commonly during infections and in medical conditions associated with inflammation (Meyers et al., 2005; Huffman et al., 2006; Bower, 2007; Davis et al., 2008). Fatigue can also be elicited in humans by administration of endotoxin (Bahador and Cross, 2007). In our subjects, MADRS Item 7 (Lassitude) changed in most subjects, as did the Vigor-Activity and Fatigue-Inertia clusters of the POMS. In cancer, fatigue has been associated with blood levels of IL-1 (Greenberg et al., 1993), IL-6, and TNF (Meyers et al., 2005), although there have been several negative studies as reviewed in (Miller et al., 2008). A quantitative review of cancer studies found a correlation between fatigue and blood levels of IL-6, but not TNF or IL-1 (Schubert et al., 2007). Fatigue and psychomotor slowing occur frequently during IFN- $\alpha$  treatment (Asnis and De La Garza, 2006; Capuron et al., 2009) which leads to increased IL-6 levels both peripherally and

centrally (Loftis et al., 2007; Raison et al., 2008). In humans, fatigue can be elicited directly by administration of IL-6 (Spath-Schwalbe et al., 1998). Taken together, these data suggest that IL-6 mediates the effects of illness, endotoxin, and IFN- $\alpha$  on fatigue. Recent imaging studies of immune-induced fatigue implicate the nigrostriatal pathway, a dopamine pathway that facilitates movement and drives motivational behavior (Cools, 2008). In IFN- $\alpha$ -induced fatigue there was increased activity in the left nucleus accumbens and putamen (Capuron et al., 2007), and in subjects who received a typhoid vaccine, psychomotor slowing correlated with activity in the substantia nigra and IL-6 levels (Brydon et al., 2008). Although most data indicate a role for IL-6, in patients receiving docetaxel, a chemotherapeutic agent for which fatigue is the dose-limiting side-effect, blocking TNF with etanercept decreased docetaxel-induced fatigue (Monk et al., 2006). Fatigue is also common in autoinflammatory disorders which are characterized by excessive IL-1 activity (Dinarello, 2009).

### 8.2. Immune-induced fatigue in rodents

Fatigue in humans is the feeling that it takes an effort, physical and mental, to engage in activities. This is difficult to model in rodents, however, a reasonable proxy is to measure how long it takes a rodent to tire from physical activity. In rodents endotoxin-induced reductions in wheel-running are blunted by the administration of antibodies against IL-6 (Harden et al., 2006), consistent with the human data on IL-6 discussed above. When administered i.c.v., IL-1, IL-6, and TNF all reduced wheel-running (Netea et al., 2007; Harden et al., 2008), and TNF deficiency or antagonism increases running time (Netea et al., 2007), suggesting that in the brain multiple inflammatory cytokines can induce fatigue. In summary, endotoxin administration reliably induces fatigue in humans and is therefore a good experimental model of this symptom. Antagonists of IL-6, IL-1, or TNF may prove useful therapies for fatigue in depression and other conditions, and novel compounds could be tested using endotoxin-induced fatigue paradigms.

## 9. Cognition

### 9.1. Immune-induced cognitive impairment in humans

Cognitive impairment, including difficulty with memory and concentration, is common in depression (Simons et al., 2009). During acute respiratory tract infection, speed of accessing stored memories is reduced (Bucks et al., 2008). It is well-known that sepsis can cause delirium (Pisani et al., 2007), and in patients with myelogenous leukemia or myelodysplastic syndrome blood levels of IL-6 were associated with poorer executive function (Meyers et al., 2005). In humans low-dose endotoxin administration impaired both immediate and delayed recall, but did not affect attention or executive functions (Reichenberg et al., 2001), while administration of IL-6 impaired concentration (Spath-Schwalbe et al., 1998). Interestingly, during IFN- $\alpha$  treatment no cognitive impairment has been demonstrated (Fontana et al., 2007), while typhoid vaccination does impair concentration (Harrison et al., 2009a,b). It thus appears that endotoxin may be a useful paradigm to experimentally induce mild cognitive deficits.

### 9.2. Immune-induced cognitive impairment in rodents

In rodents, endotoxin disrupts acquisition of learning, but does not impair performance if task has already been learned (Aubert et al., 1995). Mice deficient in IL-6 are refractory to endotoxin-induced working memory impairment. In these mice increases in plasma IL-1 and TNF levels were the same as in wild-type mice, but IL-1 and TNF levels in hippocampus were attenuated by IL-6

**Table 6**  
Immune-induced depressive symptoms.

Symptom	Endotoxin	Interferon- $\alpha$	Typhoid vaccine
Depressed mood	+/-	++	+
Markedly diminished interest or pleasure	+/-	+	?
Weight loss or decrease in appetite	+	+ <sup>a</sup>	?
Insomnia	-	-	?
Psychomotor retardation	+	++	+
Fatigue or loss of energy	+++	++	+
Feelings of worthlessness or excessive or inappropriate guilt	-	-	?
Diminished ability to think or concentrate, or indecisiveness	++	-	+
Recurrent thoughts of death, recurrent suicidal ideation	-	-	?

<sup>a</sup>Independent of the presence of other depressive symptoms.

deficiency (Sparkman et al., 2006), indicating that IL-6 is involved in immune-to-brain signaling during endotoxin-induced hippocampal dysfunction. Endotoxin-induced memory deficits were associated with loss of neurons in hippocampus and prefrontal cortex (Semmler et al., 2007), and in rats with endotoxin-induced delirium, gene expression of inflammatory mediators was most pronounced in the hippocampus (Wolff et al., 2009). These data are consistent with the memory functions of this brain region. Endotoxin administered i.c.v. for 28 days impaired spatial memory and caused increases in IL-1 and TNF expression in the basal forebrain and hippocampus (Hauss-Wegrzyniak et al., 1998), indicating that the effect of endotoxin on memory may involve TNF and IL-1 produced locally in the hippocampus, consistent with the ability of endotoxin to induce expression of IL-1 and IL-6 in hippocampal slices (Hellstrom et al., 2005). In neonatal rats, the effect of endotoxin on memory was attenuated by ICE blockade (Bilbo et al., 2005), indicating that IL-1 mediates this. The inhibitory effects of endotoxin on neurogenesis was blunted by indomethacin (Monje et al., 2003), and the COX-2 inhibitor rofecoxib reduces the effects of endotoxin on cognition (Jain et al., 2002), demonstrating a role for prostanoids. For readers interested in further information about the physiologic role of cytokines in cognition we recommend a recent review (McAfoose and Baune, 2009). In summary, in rodents peripheral inflammatory stimuli have profound effects on cognitive function, and in humans the effect of endotoxin administration on cognition may be an adequate paradigm of depression-like cognitive deficits, while this may not be the case for the IFN- $\alpha$  model. Because neuropsychological measures of various domains of cognition are more “objective” than measures of subjective psychiatric symptoms, endotoxin-induced mild cognitive deficits may be a useful experimental paradigm to test the effect of new medications on cognition.

## 10. Self-worth, hopelessness, and other symptoms of depression

In our experience with endotoxin administration, subjects do not experience feelings of worthlessness, hopelessness, guilt, or suicidal ideation. In the recent study by Eisenberger et al. there was a change in the POMS-D cluster which does include questions about worthlessness and hopelessness, however, as discussed above, the change on this cluster was very small and possibly not clinically significant. The absence of an effect of endotoxin on these symptoms is consistent with the recent study on IFN- $\alpha$ -induced depression, in which the score on the HDRS items on guilt and suicide were not different between IFN- $\alpha$  treated depressed and non-depressed patients, although those items were different in idiopathic depression (Capuron et al., 2009). Therefore, endotoxin administration does not seem an adequate paradigm to mimic depressive symptoms that have to do with negative views of self, past, present and future. Since such symptoms are obviously

impossible to model in rodents we do not know whether immune system activation can induce similar mental states in rodents. Symptoms of anxiety are frequently co-morbid with depression, although not considered a diagnostic criterion according to DSM-IV. In human subjects one study found that endotoxin administration induced anxiety as measured by the State Anxiety Inventory (Reichenberg et al., 2001). In rodents, administration of endotoxin or inflammatory cytokines have been shown to decrease open field activity (Larson and Dunn, 2001) and induce other anxiety-like behaviors (Lacosta et al., 1999), while other studies found inconclusive effects of endotoxin on anxiety-like behaviors (Swiergiel and Dunn, 2007).

## 11. Summary and conclusions

Endotoxin administration in human subjects is a relatively safe procedure that induces specific dose-dependent symptoms: at higher doses (>1 ng/kg), flu-like symptoms such as fever, chills, myalgias, headache, and nausea predominate, while at lower doses (<1 ng/kg), symptoms such as fatigue, reduced appetite, and cognitive impairment occur (see Table 6 for a comparison with the IFN- $\alpha$  model). These symptoms are similar to symptoms seen in idiopathic depression. The effects of endotoxin on sleep do not resemble sleep disturbances seen in depression, and endotoxin does not produce other depressive symptoms such as worthlessness, hopelessness, and suicidal ideation. Whether endotoxin administration produces depressed mood or anhedonia, the two core symptoms of depression, needs to be explored further. A validated model of acute immune-depression would be extremely helpful as it could be used for proof-of-concept studies that could lead to the discovery of new antidepressant targets (Gelenberg et al., 2008), to screen orally available medications that target kinases of the intracellular pathways involved in cytokine signal transduction (Gaestel et al., 2009), and for molecular and functional imaging studies aimed at identifying the brain regions involved in producing each specific symptom induced by innate immune system activation.

## Disclosure/conflict of interest

Neither N.D. nor J.H. has received any income or financial support from any entity, or has any personal financial holdings, that could be perceived as a potential conflict of interest.

## Acknowledgments

We would like to thank George Heninger for thoughtful discussions on this topic, the nursing staff of the Yale Clinical Neuroscience Research Unit for their expertise and care during our endotoxin experiments, the research pharmacist Kevin Pohl for preparing endotoxin for our experiments, and Anthony Suffredini at the National Institutes of Health Clinical Center for providing the

standard reference endotoxin. This publication was made possible by CTSA Grant Number UL1 RR024139 from the National Center for Research Resources (NCRR), a component of the National Institutes of Health (NIH), and NIH Roadmap for Medical Research.
